Joining of Metal Matrix Composites

Introduction to Metal Matrix Composites

Metal Matrix Composites, if designed and processed judiciously, can display the unique combination of properties of the matrix metal or alloy and the reinforcing materials. MMCs can, for example, display high thermal and mechanical response when compared to their monolithic metallic counterpart. In spite of many virtues, the applications of MMCs as structural material is limited due to the challenges in producing good quality weldments. The basic problem in welding the MMCs is the nature of the matrix reaction with the reinforcement at high temperature associated with the molten weld pool. This interaction of the matrix with reinforcement, if not controlled, leads to embrittlement of the matrix and decrease in the matrix/reinforcement interface strength. Hence, the fusion welding processes viz., Gas Tungsten Arc Welding (GTAW), Gas Metal Arc Welding (GMAW), Laser Beam Welding (LBW), etc., are difficult to use to join MMCs.

In this context soldering, brazing and solid state joining processes viz., friction welding, diffusion bonding, friction stir welding, etc., are ideal techniques for joining MMCs since in these techniques the high temperature and melting of the base material is avoided. When compared with solid state welding, soldering and brazing have critical applications, i.e., joining precisely intricate parts and joining large surfaces, respectively.

Classification of MMCs

Metal matrix composites can be classified based on the type of reinforcement used namely: particulate, whisker or short fiber, continuous multi filament and continuous mono filament and interconnected filaments (Campbell, 2011); the matrix material used, and primary and secondary processing techniques used.

Designation of Metal Matrix Composite

For metal matrix composites having metal or alloy matrix and reinforced with reinforcement in various percentages are designated as below:

Alloy (or) Metal/Particle/Percentage of reinforcement
Example: AA6061/TiO₂/20p

Where, p is used to represent particulates, w is used to represent whiskers and f is used to represent fiber. In this example, 6061 series aluminum alloy matrix is added with 20% of TiO₂ reinforcement particles to form the AMMC (Aluminum Metal Matrix Composite) (Ureña *et al.*, 1997).

Mechanical and Metallurgical Aspects of MMCs

MMCs normally exhibit improved strength than their metallic counterparts. The extent of increase in strength, however, is not very significant when compared to their increased elastic modulus (Mallick, 2016).

The rule of mixture expression for computing elastic modulus of MMCs can be written as:

$$E_c = V_p E_p + V_m E_m \quad (1)$$

Where, E_c is the moduli of the composite, E_p is the moduli of the particulates, E_m is the moduli of the matrix, V_p is the volume fraction of particulates, and V_m is the volume fraction of the matrix.

Eq. (1) is reasonably accurate for the continuous reinforcement, while Eq. (2) is appropriate for the discontinuous reinforced MMCs (Halpin, 1984).

$$E_c = E_m \left(1 + 2sqV_p \right) / \left(1 - qV_p \right) \quad (2)$$

Where, s is the aspect ratio of the particulate and

$$q = (E_p/E_m - 1) / (E_p/E_m - 2s) \quad (3)$$

The Young's modulus is dependent upon the volume fraction of reinforcement and it is not much affected by the distribution of the particles. The increase in strength of the MMCs containing micron and sub-micron size ceramic particulates is associated with decrease in percentage of elongation. The ductility of the MMCs for these length scales is strongly influenced by the distribution of the

particles. The homogeneity of the microstructure of the MMCs is strongly influenced by the type of primary and secondary processing of the material. The recrystallization of grains in MMCs is affected during heat treatment, by the volume fraction of the particles and their size. The reactivity between the matrix and reinforcing particles influence the choice of processing to be selected.

Applications of Metal Matrix Composites

In almost the past four decades MMCs are mostly made using aluminum and its alloys as matrix material, as they replaced heavier cast iron and steels in many applications. Magnesium based MMCs are emerging as an alternate light weight replacement for aluminum based MMCs. The continuous reinforcements like boron fibers and graphite fibers are restricted to aerospace applications, due to their high cost, lack of secondary fabrication capabilities and non-availability in various shapes (Mallick, 2016). The cheap reinforcements namely short staple mullite fiber and Al_2O_3 are used to enhance wear resistance through selective reinforcement of engine parts like the ring land area of diesel engine pistons (Dinwoodie *et al.*, 1985; Stacey, 1988; Donomoto *et al.*, 1983). Discontinuously reinforced MMCs generally use particulates as reinforcement. The ceramic particles like Al_2O_3 and SiC are used in MMCs due to their low cost and ease of fabrication using existing conventional fabrication machineries. By virtue of their low aspect ratio, they impart isotropic properties similar to their matrix metal/alloy and hence are used in commercial fabrication of brake rotors, bicycle frames, wear resistant studs, cylinder liners, thrust plates, wrought and cast components, and thermal spray coatings (Mallick, 2016). The graphite/aluminum discontinuous reinforced aluminum composites (DRAs) are used in tribological application as they display superior wear resistance, anti-friction and anti-seizure behavior (Campbell, 2011). Generally, the volume fraction of reinforcement is kept less than 25 vol%. MMCs with more than 25 vol% reinforcement are used in applications like thermal management systems, electronic packaging and high temperature applications, which require high thermal conductivity and low coefficient of expansion (Lloyd, 1994; Mallick, 2016).

Joining of MMCs Through Fusion Techniques

Challenges in Fusion Welding of MMCs

The welding of MMCs through fusion welding processes namely Gas Tungsten Arc Welding (GTAW), Gas Metal Arc Welding (GMAW), Laser Beam Welding (LBW), Electron Beam Welding (EBW), etc., pose a challenge due to the following issues (Ellis, 2007):

- (1) High Viscosity of Molten MMC: Due to the presence of reinforcing particles or fibers in the matrix the viscosity of the molten weld pool of the MMCs is higher than that of the matrix alloy. This makes it impossible, to manipulate the weld pool and to ensure the homogenous distribution of the particles. As the temperature of the weld pool is increased the viscosity can be reduced but metallurgical reactions between the particles and the matrix increases. The viscosity is also affected by the amount of reinforcement and their size and shape. The use of autogenous gas tungsten arc welding, i.e., without filler wire, is effective but it behaves like brazing, yielding minimal dilution in the fusion zone and the heat affected zone of the parent MMC material.
- (2) Reinforcement Particle/matrix Reaction: The differences in melting point of reinforcement particles/fibers and the matrix, high thermal expansion co-efficient differences and difference in thermal cycles causes thermal stresses in welding and triggers reaction between the reinforcement particles and the matrix (Bhattacharyya *et al.*, 1992). At high temperatures, the reinforcing particles react or dissolve in the matrix and form detrimental compounds upon cooling. Mostly these products of particle/matrix reaction have needle shaped morphology which act as stress concentration points during loading and make MMCs prone to corrosion (Dahotre *et al.*, 1991). These reactions can be controlled easily by using optimal process parameters and minimal weld heat in GTAW and GMAW where inert gas shielding is provided. This reaction can be controlled by optimizing the process parameters in power beam welding processes like EBW and LBW, wherein LBW is much sensitive, but the former is almost immune as the process is carried out in vacuum. The selection of suitable electrode/filler wire compatible with the chemical composition of the matrix slows down the reaction between particles and the matrix. The reaction between particles and matrix is not been reported in solid state welding, in particular, the resistance spot welding.
- (3) Segregation of Reinforcing Particles: The segregation of reinforcing particles occurs in micro and macro scale during welding. In the GTAW and GMAW, the particles are pushed by the solidification front, resulting in a micro-scale segregation of reinforcing particles. This behavior is not observed in the LBW and EBW which have rapid thermal cycle (Dahotre *et al.*, 1991). In the case of resistance spot welding, macro segregation is observed where a large variation in the distribution of the particles exists across the weld nugget. The mechanism causing this heterogenous distribution of particles in resistance spot welding is not clear. This can be controlled by selection of proper process parameters (Gittos and Threadgill, 1991).
- (4) Release of Occluded Gases: The occluded gases particularly hydrogen poses a problem in the MMCs fabricated through powder metallurgy process. During fusion welding, the melting of MMCs causes the release of occluded gases from the solid solution which causes embrittlement of the heat affected zone and porosity in the weld fusion zone and heat affected zone. The occluded gases can be removed by vacuum degassing of the metal powders before the fabrication of the MMC (Ellis, 1996).

The application of fusion welding techniques to weld MMCs has its own challenges as the high temperature involved in fusion welding sets ideal conditions for chemical reaction between matrix and the reinforcement particles leading to the formation of intermetallics, oxides and change in grain size. These conditions are detrimental for the strength of the MMCs (Ureña *et al.*, 1997; Holcomb, 1991). The homogeneous distribution of the reinforcement particles is interrupted in the MMC molten pool and likely to be absent in the joint. The use of a MMC filler rod or the post weld treatment (spheroidization treatment) have not much effect in improving the properties or minimizing the heterogeneous distribution of reinforcement or its absence in the joint or their agglomeration (Clyne and Withers, 1993). Hence the solution to these limitations is to apply heterogeneous joining techniques like brazing where low fusion temperature filler is used to join the metal matrix composite. Mostly it is applied in joining aluminum based MMCs (Sugiyama, 1989).

Low Heat Intensity Fusion Welding: Gas Tungsten Arc Welding and Gas Metal Arc Welding

The low intensity heat input fusion welding processes that are commonly used to join MMCs are Gas Tungsten Arc Welding and Gas Metal Arc Welding. As in metals and alloys, the alternating current is used while welding aluminum (2xxx and 6xxx) based MMCs since it breaks down the oxide film on the surface of the metal. The Discontinuously Reinforced Aluminum Matrix Composite (DR-AMC) having SiC as reinforcing particles are welded with high silicon filler wires such as ER 4047. Similarly in the case of MMCs with Al₂O₃ reinforced particles, high magnesium filler wire are used (Ellis, 1996). The presence of reinforcing particles in the MMC weld pool hinders their homogenous mixing and leads to agglomeration, segregation and dewetting. The addition of fibers in 6061 Al-B MMC and welding autogenously caused dissolution and filament (fiber) fragmentation (Laurent *et al.*, 1987). This could be solved by using silicon rich filler which protects the outermost layers of Boron filaments and improve their wettability. AA6061 aluminum alloy having 15 vol% SiC of 10 µm size when welded using GTAW yielded good quality welds (Xi-he *et al.*, 2009). The addition of 50 vol% helium with argon of 99.99% purity and the use of Al-Si filler wire resulted in a stable arc with no spatter, higher energy density, deeper weld penetration, and the undesirable interface reactions were prevented thus simultaneously improving the mechanical properties of the welded joints.

During welding of aluminum based MMCs containing SiC reinforcing particles, the liquid-phase processing leads to conditions favorable for interfacial reactions to take place between aluminum and SiC to form needle like phases namely Al₄C₃, Al₄Si₂C₅, Al₄SiC₄, and free silicon (Ureña *et al.*, 2000; Shin *et al.*, 1997; Viala *et al.*, 1993; Ahearn *et al.*, 1982). The formation of Al₄C₃ occurs at the expense of SiC particles added for reinforcing the matrix.

The needle-like Al₄C₃ is prone to hydrolysis leading to corrosion of the MMCs (Park and Lucas, 1997). The free silicon creates Al-Si eutectic aggregates on the particle-matrix interface and at the grain boundaries of the matrix, causing loss of ductility. The welding at lower temperatures could prevent/minimize the interfacial reactions and thereby producing good quality welds.

The gas metal arc welding of AA7020 (Al-Zn-Mg) and AA7005 reinforced with 10 vol% of Al₂O₃ particles was done using ER44043 (Al-Si) and ER5356 (Al-Mg) fillers. In the welds carried out with ER44043 filler, the formation of hypoeutectic interdendritic structures having Al-Si precipitates in the interdendritic locations was observed (Salazar and Barrena, 2003). The post weld T6 artificial aging converted the microstructure to one with spheroidized morphology with recrystallized aluminum, which increased the toughness. Further, the post weld heat treatment caused precipitation of the hardening Mg₂Si phases and improved the hardness of the welded joint (Gómez de Salazar and Barrena, 2002).

The joints welded with ER5356 filler exhibited dendritic structure with the formation of primary aluminum and secondary phase (Mg₂Si) in the inter-dendritic location. This was caused due to the excess magnesium in the filler wire. The presence of Al₂O₃ particles decreased the thermal diffusion and thus maintained the MMC at high temperature for long period. This annealing condition caused dissolution of hardening phases and loss of mechanical properties which was reversed upon post weld T6 aging heat treatment.

The nitrogen gas plasma arc welding of SiCp/Al MMC was used to carryout in situ alloying to improve the mechanical properties of welded joints. The use of titanium as a filler material for the in situ alloying eliminated the formation of the detrimental Al₄C₃ phase in the MMC. The welding heat caused the recrystallization of the aluminum matrix. Since the free energy involved in the formation of TiC is much lower than that of Al₄C₃, the TiC formation occurred readily thus suppressing the formation of Al₄C₃. Similarly, the reaction between aluminum and nitrogen from the ionized gas takes place yielding AlN₂ and TiN, and suppressed the formation of Al₄C₃.

When compared with TiC and TiN, TiN has lower free energy and hence TiN is easily formed. The formation of new hard phases TiC, TiN, Al₃Ti, and Ti₅Si₃, compensated the loss of SiC due to its dissolution in the weld pool and improved the mechanical properties.

High Heat Intensity Fusion Welding: Laser Beam Welding and Electron Beam Welding

The high heat intensity welding processes are characterized by the low heat input associated with the fast thermal cycle, such as in the Laser Beam Welding and Electron Beam Welding processes (Ellis, 1996). The laser beam coupling, i.e., the interaction of the beam with the material is around four times higher for MMCs when compared with the monolithic alloys. Hence the laser beam

welding is more effective on MMCs. Majority of laser beam welding are carried out on Aluminum/SiC MMCs using Continuous Wave (CW) CO₂ laser and Pulsed Nd:YAG laser.

The A356–20% SiC MMC when welded with CO₂ laser in key-hole mode yielded welded joints showing formation of Al₄C₃ through dissolution of SiC and Si enrichment of the aluminum matrix and thus resulting in loss of toughness and causing brittleness of the joint (Bassani *et al.*, 2007). Even though the amount of Al₄C₃ can be minimized by choosing proper welding parameters, but the formation of Al₄C₃ phase cannot be totally avoided. The conduction mode with diode laser caused much lower increase in temperature and hence the SiC dissolution was limited and their uniform distribution produced joints with good mechanical properties. The only drawback in the diode laser is lack of penetration, which can be compensated by using high power diode lasers.

The in-situ alloying with titanium while joining SiCp/6061 Al MMC using CO₂ laser was found to be effective in completely eliminating the formation of the needle-like detrimental aluminum carbides (Wang *et al.*, 2000).

The laser and electron beam welding of fine grained Al6061/SiC MMC with 1%, 5%, and 20% SiC, produced welded joints exhibiting High Strain Rate Superplasticity (HSRS). The presence of SiC particles improved the beam coupling of the laser and hence the welding was of better quality in LBW, than the EBW process. The fusion zone of LBW welded Al6061/SiC MMC exhibited occasionally shallow cavities on the weld cap whereas in the case of EBW a V shaped notch was observed (Huang *et al.*, 2001).

The increased SiC content increased the laser beam absorption efficiency but it caused formation of Al₄C₃ and embrittlement of the welded joints. Hence the fine grain structure was lost and efficiency of HSRS weldments was lost. Thus the LBW and EBW for HSRS is not practically feasible.

The CO₂ laser beam welding of TiB₂ particles reinforced aluminum matrix composite exhibited agglomeration in the middle of the weld bead. The laser energy absorption efficiency of TiB₂ particles is greater than the surrounding aluminum matrix and hence they melt and merge together to form clusters of TiB₂. The partially molten TiB₂ particles react with the molten aluminum matrix resulting in the interfacial reaction. AlB₁₂ and Al₃Ti were formed as a result of reaction and were reported to be harmful for the welded joints. Meng *et al.* (2013) also observed that the aluminum near to the key hole of the laser gets vaporized and the thermal stress was caused in the TiB₂ which are inside and around the key hole, as they undergo uneven expansion due to sharp temperature gradients.

The pulsed Nd-YAG laser welding of SiC reinforced Al–Cu–Mg MMC proved that good quality welds can be produced by controlling the laser parameters such as laser intensity and a long pulse-on time. This ensured minimal formation of Al₄C₃ and welding defects like thermal cracking and porosity (Yue *et al.*, 1997).

The YAG solid pulsed laser welding of silicon carbide whisker (SiCw) reinforced 6061 Al MMC yields weld strength of around 70% of the parent MMC. This was realized by improving the weld quality by decreasing the heat input of the weld pool and increasing the silicon carbide content in the weld pool (Niu *et al.*, 2006).

The addition of a 0.05 mm thick foil of 99.99 wt% pure Zr in the weld zone improved the tensile strength of the fiber laser welded 10 vol% SiC particles (SiCp) reinforced MMC. The porosity in the weld zone was eliminated by the alloying with Zr. The addition of Zr in the weld zone improved the wettability of the SiCp and reduced the viscosity of weld pool and hence permitted the escape of the bubbles from the weld pool. Zirconium reacted with SiCp and formed ZrC phase which was dispersed throughout the weld zone and improved the properties of the welded joints (Long *et al.*, 2020).

The dissimilar metal joints of 6061 aluminum alloy and MMC reinforced with TiB₂ particles using Nd-YAG pulsed laser was influenced by the laser power followed by laser frequency and welding speed. The phases such as Al₂Ti, Fe₂Si, and Al_{0.5}Fe₃Si_{0.5} and free aluminum were formed in the weld zone with the decomposition of TiB₂ particles upon reaction with Al. The unreacted TiB₂ particles solidified and the excess TiB₂ particles segregated at the grain boundaries by the molten Al. The TiB₂ particles were well wetted by the molten aluminum matrix which enhanced the corrosion resistance of the weld zone (Dai *et al.*, 2019).

The YAG laser welding of AA1100–16vol% B₄C MMC resulted in the decomposition of B₄C and the formation of needle-like AlB₂ and Al₃BC phases. Alloying with a 150 µm thick Ti foil decreased the needle like phase formation and improved the tensile strength. Whereas, the use of filler wire along with Ti alloying, led to its segregation and loss of tensile strength (Guo *et al.*, 2012).

Joining MMC Through Solid State Techniques

Friction Welding Processes

Friction welding is one of the popular technique to join MMCs. Friction welding is of various types such as rotary, inertia and linear. The friction between the moving components produces heat which causes the plastic extrusion-forging of the mating parts. The general behavior of friction welding is that, the reinforcing particles either break or crushed at the interface of the components in movement or at the tool-component interface. The heat affected zone tends to be softened leading to reduction of hardness (Ellis, 1996).

Friction Stir Welding (FSW) involves a rotating tool with a pin plunged into the joint interface resulting in frictional heat leading to the plasticizing of the metal and its extrusion and recirculation causing the formation of the welded joint (Vijay and Murugan, 2010). The rotating pin and shoulder irons the extruded and recirculated plasticized metal and forms a stir zone where the joint is formed. There is exhaustive literature on the influence of tool profile and the FSW process parameters on the

microstructure and the mechanical properties of various AMCs (Chen *et al.*, 2009; Fernandez and Murr, 2004; Wert John, 2003; Marzoli Gambaro *et al.*, 2006).

The profile of the pin and shoulder ensures sufficient frictional heat generation and formation of the weld nugget or joint. The proper selection of the FSW process parameters yields defects free joints, which otherwise end up with worm holes, tunnel defects etc.

The friction stir welding of AMC with 10 wt% of TiB_2 with a straight square pin profile yielded a narrow stir zone having a fine grained microstructure with homogeneous distribution of the TiB_2 particles, much better than the parent AMC and exhibited good mechanical properties (Vijay and Murugan, 2010).

The friction stir welded 20 wt% $\text{B}_4\text{Cp}/6061 \text{ Al-T6}$ AMC processed with a threaded cermet tool caused fragmentation and blunting of the B_4C particles which were homogeneously distributed in the nugget zone. This was due to severe particle/pin interaction and resulted in dissolution of the fine precipitates in the nugget zone and the loss of tensile strength of the friction stir welded joints. The use of optimized FSW parameters improved the weld quality and the mechanical properties. Further improvement of the properties was realized through artificial aging which resulted in re-precipitation and improvement of the mechanical properties (Li *et al.*, 2019).

The friction stir welding was also applied to join bulk metals, alloys, MMCs and dissimilar materials. The same FSW in a modified form called as Friction Stir Processing (FSP) was used to do surface engineering of the materials. In this context, the FSP was carried out to produce Surface Composites (SC), i.e., MMC was confined to the surface of the metal based material.

AA7050-T7451 (Al-Zn-Mg-Cu) alloy processed by FSP was butt welded with FSW. They on further friction stir welding yielded uniform distribution of the hybrid reinforcement particles of TiB_2 , Al_2O_3 , Mg, and Zn and also exhibited uniform hardness. Incidents of minute tunneling defects and Incomplete Root Penetration (IRP) were observed, which can be prevented with selection of suitable FSW parameters (Haider *et al.*, 2019).

The rotary friction welding of A6061 with 10 vol% Al_2O_3 with the similar AMC and with the base A6061 alloy yielded good results indicating that friction welding is ideal for welding MMCs. The increase in friction pressure decreased the thickness of the intermetallic film and encouraged disruption and removal of the oxide films from the joint interface through the formation of flash thus directly increasing the tensile strength of the welded MMCs (Maldonado, 1997).

The dissimilar and similar linear friction welding (LFW) of 2024 Al alloy and 2124 Al/SiCp MMC resulted in good weld joint efficiency with a decrease in elongation. This decrease in elongation was attributed to orientation of the plastic flow of metal in the Thermo-Mechanical Affected Zone (TMAZ) which undergoes severe plastic deformation. The weld zone exhibited ultra-fine microstructure with uniform distribution of the reinforcement particles (Ceschini *et al.*, 2010).

Solid State Diffusion Bonding of MMCs

The hard protruding reinforcing particles existing in the planar interface penetrates into the soft matrix leading to ideal bonding. Situation of a non-planar interface could occur when the protruding reinforcing particles between the planar bond line at the interface of the faying surface interlock and thus contributing to higher bond strength (Shirzadi *et al.*, 2001). The increase in bond strength was attributed to the reinforcing particles rupturing the oxide layer in their vicinity (Partridge and Dunford, 1991; Shirzadi, 1998).

Joining MMC Through Bonding

Diffusion bonding of MMC can be carried out through conventional transient liquid phase (TLP) bonding, solid state diffusion bonding and the temperature-gradient transient liquid-phase diffusion bonding (Shirzadi *et al.*, 2001).

In diffusion bonded MMC-MMC joints the bond line is studied keeping in view the interfaces, namely; matrix-matrix interface, matrix-particle interface, and particle-particle interface. The volume fraction of the reinforcing particles in the faying surface and their distribution, decides the area fraction of the bond line interface (Partridge and Dunford, 1991).

Transient Liquid-Phase (TLP) Diffusion Bonding of MMCs

In transient liquid-phase diffusion bonding, an interlayer is introduced between the faying surfaces. The interlayer may have a lower melting point or form a liquid eutectic phase which lowers the melting point of the matrix in its vicinity. This causes diffusion between the faying surfaces and the adjoining liquid interface and solidifies isothermally at the bonding temperature at which the material is soaked. During this process the oxides, impurities and reinforcing particles get agglomerated and get pushed forward towards the planar bonding line by the advancing solid-liquid boundaries (Maddrell, 1989).

Temperature-Gradient TLP Diffusion Bonding of MMCs

In temperature-gradient TLP diffusion bonding a temperature gradient is maintained during TLP leading to the formation of non-planar bond line having higher metal to metal interface (Assadi *et al.*, 2001). These interfaces are wavy having sinusoidal to

dendritic morphology, with unbounded areas and voids in between them. By controlling the temperature gradient, thickness of interlayer and size of reinforcing particles, strengths equivalent to the parent MMC material can be achieved with high metal-to-metal contact (Zhai and North, 1997). Hence comparing solid-state bonding and TLP; this technique produces reliable high strength joints.

Adhesive Bonding of MMCs

The SiCp reinforced aluminum MMC sheets can be bonded at room temperature using adhesive bonding method. The adhesive bonding does not involve any thermal cycle which causes undesirable chemical reactions producing detrimental intermetallic compounds. Even though the adhesives such as toughened acrylic, epoxy resin, nitrile phenolic etc. produce good bonding, but its effectiveness depends on the surface pretreatments. The surface pretreatment such as chromic acid anodizing and silane pretreatments are established to produce good bonding of the substrate with the SiC particles which hook themselves to the pretreated surface. But the disadvantage of these pretreatments is the poor durability of the bonds and they are detrimental in nature. Hence the etching or abrasion of the bonding surfaces is sufficient to yield good bonding for adhesive bonded MMCs (Ellis, 1996, 2007).

In the case of Glass Laminate Aluminum Reinforced Epoxy (GLARE) fiber metal laminates, thin layers of metal sheets are stacked in between unidirectional fiber layers which are bonded to the metal layers using adhesive. The pretreatment of the metal fraying surface involves chemical cleaning through phosphoric acid anodizing or chromic acid anodizing process. The chemically cleaned surfaces are made durable and corrosion resistant by treating with corrosion inhibiting primer. The bonding between the adhesive and the fibers are very strong and the failure occurs through cohesive adhesive failure. The GLARE possesses good resistance to fatigue crack propagation and good strength at a lighter weight and cheaper cost when compared with the bulk metal. In order to manufacture the GLARE at cheaper cost and produce compatible forms and shapes, self-forming technique (SFT) is used (Vlot and Gunnick, 2001).

Joining Using Brazing and Soldering

Brazing of MMCs and Using MMCs for Joining

The brazability of MMCs is dependent on the wettability of the filler material by the MMC matrix, which is influenced by the following:

- (1) The liquidus temperature of the filler metal. The filler metal having a liquidus temperature lower than melting point of the constituents of the matrix. The filler with eutectic composition is regarded as having the best wettability. The wettability of the filler droplet is governed by the spread ratio (SR) and contact angle (θ). The spread ratio is the ratio between total area wetted by the molten metal, to the original area of the filler metal (Humpston and Jacobson, 1993). The contact angle is the angle made by filler drop with the surface of the matrix. Generally an angle less than 90° is advised and contact angle lower than 20° is preferred for brazing (Nicholas, 1989).
- (2) The viscosity of molten filler. The viscosity of the molten filler decides the required wettability or the flow out of the filler from the joint leading to voids and unwanted wetting on the parts other than the joint. At high temperatures, the viscosity of the molten filler is affected by the percentage of ceramic particles. The presence of reinforcement causes formation of solid phases in the molten filler drop and reduces the spreading and diffusion of the molten filler on the matrix metal (Klomp, 1989).
- (3) The dissolution of the elements from the matrix into the molten filler metal reduce its wettability due to the formation of primary solid phase in the presence of ceramic reinforcement particles.
- (4) Increase in brazing cycle causes changes in the grain size, which affects the properties of the MMC.

Several brazing techniques have evolved to braze MMCs and a few of them are discussed below:

- (1) Vibration assisted brazing: The SiCp/A356 MMC brazed using an experimental setup that could bond the joint at 375°C with the assistance of mechanical vibration showed that the oxide layer was disrupted and removed due to vibrations during brazing with Zn–Al eutectic filler alloy. Even though the bonding was realized, it had porosity. The porosity was removed upon continuously heating the joint upto 520°C leading to an enhancement in strength beyond that of the base MMC material (Yan *et al.*, 2008).
- (2) Electromagnetic field aided brazing: The behavior of SiC particles in MMCs during joining is critical and hence it has to be kept under control. In this connection a new method of brazing called as electromagnetic field aided brazing (EMFAB) was developed. In the EMFAB brazing of SiCp/A356 MMC using Zn–Al filler alloy, the magnetic intensity of 0.5T aided in the homogeneous distribution of SiC particles in the brazing seam with room for the inherent nature of segregation at the joint interface (Yu *et al.*, 2010).
- (3) Vacuum brazing: Brazing being a heterogeneous joining process is preferable in joining MMC/MMC and MMC/alloys. The joining of SiCp/6063Al MMC with Fe–Ni alloy using vacuum brazing with a filler metal Ag47–Cu18–In17–Sn17–Ti–1 was

carried out at a temperature of 580°C. The soaking of the filler and the joint material at 580°C for 30 min under vacuum created ideal conditions for the diffusion of Ag, Sn and In into the SiCp/6063 Al MMC thereby led to the formation of a good joint. But this process affected the strength of the joint when the brazing temperature exceeded 580°C (Gao *et al.*, 2016). Vacuum brazing of a titanium based alloy Ti-48Al-2Cr-2Nb and TiC/Ti metal matrix composite using Ag-28Cu filler alloy at high temperature of 850°C produced good joints with microstructure showing Ti-48Al-2Cr-2Nb/TiAl + AlCuTi/AlCu₂Ti/Ag/AlCu₂Ti/Ti₂Cu/Ti as a new MMC. With the increase of temperature the thickness of the brazing seam increased and there was a decrease in the Ag (solid solution) volume fraction and the AlCu₂Ti reaction layer disappeared followed by the formation of new phases namely Ti₃Al and Ti (Cu, Al) in the joint region, which improved the properties of the joint. However, the joints became brittle with increase in temperature to 1000°C wherein the Ti₃Al phase coarsening occurred and excess of Ti and Al diffused into the joint. Hence the increase in brazing temperature in the above system was shown to induce undesirable brittleness and loss of properties (Dongdong *et al.*, 2019).

- (4) Ultrasonic assisted brazing using MMC: In order to reduce the interfacial cracking of joints in sapphire blocks an interlayer having a sandwich structure comprising of MMC Zn-Al/(SiCp/A356)/Zn-Al was fabricated and placed below the Zn-Al filler alloy coated sapphire blocks. The whole setup was brazed under the influence of ultrasound. It was observed that the SiCp/A356 MMC was dissolved by the Zn-Al filler alloy to yield a new MMC of SiCp/Zn-Al-Si comprising of Zn-Al-Si alloy having around 40 vol% of SiC particles (Wei *et al.*, 2018).
- (5) Microwave assisted brazing using MMCs: Copper was joined by microwave irradiation using an interlayer comprising of copper powder dispersed in epoxy resin to hold the faying surfaces together and to prevent squeezing off of the inter layer. Charcoal was used as a susceptor to initiate initial heating of copper powder and due to its ability to couple with the microwaves. The joint obtained was crack free and had minimal porosity. The addition of 7% of carbon increased the hardness and aided in forming a good bond between the sandwich layer and the copper interfaces (Srinath *et al.*, 2011).
- (6) Oxyacetylene brazing for preparing MMC filler: In yet another unique study, a MMC filler material was fabricated from a WC/W₂C, Cu and Mn powder by infiltration of a nickel based bronze (74.4 wt% Cu, 15.8 wt% Sn, 3.8 wt% Mn, and 5.5 wt% Ni). The MMC filler was fabricated using oxyacetylene brazing process with an Ag alloy brazing filler metal (49 wt%Ag, 23 wt% Zn, 16 wt%Cu, 7.5 wt%Mn, 4.5 wt%Ni). This MMC was brazed to WC-Co substrate of a Polycrystalline Diamond Compact (PDC) insert. The formation of an inter diffusion zone in the brazing showed phases like AgMn₁₉, Cu-Zn, and Mn-Zn which enhanced the bonding between the WC-Co cermet and the MMC (Bouzegzi *et al.*, 2018).

Solderability of MMCs

Solderability of MMCs was investigated by many researchers. Effect of plating on the faying surface was investigated by Lu *et al.* (2012). The nickel plating of Al356-SiC composite faying surface containing 55 vol% SiC particles showed that the nickel did not react with the Al356-SiC composite substrate during electroplating and it improved the wettability of the Zn-Cd-Ag-Cu solder alloy (Lu *et al.*, 2012). The electroplating process caused formation of gas pores of around 1 µm due to probable diffusion and accumulation of hydrogen. These pores aided in the mutual diffusion of the elements in the solder alloy, Ni plating layer and the Al356-SiC composite base material thus improving the wettability and strength of the Al 356-SiC MMC and Fe-Ni-Co alloy (commercially known as Kovar) joint. The Ni electroplating of the base MMC material with 55 vol% SiC particles improved the wettability of solder which otherwise would hinder it (Ernst Mikols and Burkhard Haas, 2003; Niu *et al.*, 2003; Wang *et al.*, 2009; Niu *et al.*, 2001; Enis, 1996).

The ultrasonic assisted soldering of Al-Cu-Mg (2024 Al) AMC eliminated the oxide layer and encouraged the bonding of the Zn-Al filler and AMC having 30 vol% of Al₂O₃ particles. The soldering strength increased with increase in time of exposure to ultrasonic vibrations (Xu *et al.*, 2012).

The presence of reinforcement in AMCs makes it challenging to solder. The high temperature soldering of AA2014 series aluminum based SiC reinforced composite using Zn-Al filler alloy was carried out in the temperature range of 400–450°C. The AMC was reinforced with discrete SiC particles of 6, 13, and 20 vol%. It was observed that the aluminum with more than 10 vol% of reinforcement tend to exhibit poor wettability. The presence of alloying elements like copper and magnesium led to intergranular penetration of the filler elements by their diffusion through the grain boundaries of the base matrix with partial melting of the matrix material and thus promoting the diffusion of zinc into the matrix. In cases where low melting point solders were used, it was observed that defects like erosion and lack of penetration occurs along with reduced strength (Ureña *et al.*, 2001).

Electronic Solder Composites

The use of Lead based solder composites is challenging. Further, the environmental concern about the use of lead (Pb) in the solder is also a major concern in soldering MMC. On the contrary, lead free solder composites possess enhanced bonding and mechanical strength compared with the conventional solder alloys. The addition of nano particles, carbon nano tubes, metal meshes, etc. have been explored to produce lead free composite solder materials.

The soldering of aluminum matrix composite fabricated through Equal Channel Angular Extrusion (ECAE) with SiC, Al₂O₃ particles reinforced upto 35 vol% using tin based solders, yielded good quality joints. This was attributed to the simultaneous

application of ultrasonic vibrations and heat treatment using a tube furnace. The ultrasonic vibrations ensured homogenous distribution of the particles in the solder and there were no new phases formed since the process was carried out between 250 and 280°C with the solders melting point being around 227°C. The main strengthening mechanism was due to the ability of the particles to arrest the movement of dislocations. Further the ultrasonic process aided in increasing the wettability of the solder (Weis *et al.*, 2008).

The Sn-Bi solder reinforced with SAC-BN particles made through mechanical mixing and soldered through reflowed solder method exhibited an unique behavior of change of grain size, till the addition of 0–8 wt% of SAC-BN particles. The Sn-rich phase was increased and the increase in grain size of β -Sn matrix was observed, leading to the increase in hardness and brittleness and reduction in mechanical properties. However, the doping of SAC-BN particles above 8 wt% led to refinement of grains and improvement in the mechanical properties (Liu *et al.*, 2016).

The lead free solder Sn–0.7Cu–0.05Ni with the addition of TiO₂ particles through microwave assisted sintering powder metallurgy method with TiO₂ in 0, 0.25, 0.5, 0.75, and 1.0 wt% yielded a composite solder. The microwave assisted sintering proved to be an ideal technique to ensure the uniform distribution of the TiO₂ particles in the lead free composite solder. The presence of TiO₂ caused the reduction in thickness of intermetallic compound layer and thus leading to improved ductility, hardness and shear strength of the soldered joint (Ramli *et al.*, 2016).

Lis *et al.* (2018) investigated the use of stiffening copper and nickel thin metallic meshes within SAC305 solder joints. The results showed formation of faceted Ni₃Sn₄ intermetallic at the surface of the copper mesh – SAC 305 (CMS) solder interface and nickel mesh and SAC 305 solder (NMS) interface. It caused a fracture pattern existing partially within the solder and partly in the solder-mesh interface. This phenomenon of mesh reinforcement increased stiffness by 5% in the case of NMS and 11% in CMS and locally increased fracture resistance.

Joining of Sandwich Composite – Explosive Welding

Sandwich composite materials are made of multiple layers of materials which comprises of laminates of metal or alloy with reinforcing fibers. These laminates are bonded together by means of adhesive bonding or cladded using solid state welding process like Explosive Welding (EW). The fabrication of aluminum sandwich composite reinforced with steel wire mesh was carried out through explosive welding. The steel wire mesh placed between two aluminum plates gets bonded with negligible heat transfer from one plate to another due to rapid release of energy from the explosion. The hardness of the joining interface was increased due to the work hardening effect associated with severe plastic deformation caused by the cold pressure applied by the explosion in explosive welding process. At the same time, the hardness of the matrix away from the joint interface exhibited a reduction in the hardness (Gülenç *et al.*, 2015).

The explosive welding of LY12 Aluminum plate/reinforcing steel fiber/304 L stainless steel plate showed that the ballistic resistance of the composite increased with the increase in density of reinforcing steel fiber (Zhou *et al.*, 2014).

The cold pressure welding of a sandwich composite comprising of stacks of alternate layers of stainless steel wire meshes and aluminum foils was fabricated through explosive welding method. The bonding is between the stainless steel fibers and the aluminum foil was attributed to extrusion of aluminum foil between the fibers of the reinforcing mesh, rather than through explosive welding (Bhalla and Williams, 1977).

The results indicate that explosive welding is an alternative and effective method of joining except for the risks that are inherently associated with this kind of joining.

Non Destructive Testing (NDT) of MMC Weldments

The agglomeration of coarse reinforcing particles which are not wetted leads to degradation of strength and ductility of the MMCs (Mallick, 2016). Further, the presence of porosity and other metallurgical defects leads to unreliability of the MMC components. Hence, there is a need for non destructive evaluation of MMCs to ensure reliability. The presence of defects and quality of MMC joints are assessed by NDT techniques both quantitatively and qualitatively. The quantitative evaluation involves the assessing of defects caused by the presence of reinforcement in the matrix. The quantitative evaluation using ultrasonic testing technique with suitable contraption of using aluminum layer between the ultrasonic transducer leads to determination of the presence of reinforcing particles in spite of the signal scattering and the attenuation effects. Pulse echo ultrasound immersion test are affected by the interface zone but could detect the presence of defects. X ray radiography or a Scanning Laser Acoustic Microscope (SLAM) yields good sensitivity to the presence of defects besides the presence of reinforcing particles. The acoustic microscopy is capable of detecting micro cracks and micro porosity in the MMC. However, the x-ray radiography is not suitable for in-situ evaluation. The application of micro focus x-ray radiography aids to analyze the components as a whole whereas the misorientations of fibers and the presence of macro pores can be determined. The eddy current gets distorted due to the presence of surface irregularities which mask the presence of subsurface defects (Ellis, 1996).

The qualitative analysis of MMC joints helps to investigate the position of the reinforcement, their orientation, volume fraction and distribution in the MMC. The qualitative analysis are carried out using optical microscope, scanning electron microscope,

tunneling electron microscope, etc. The combination of qualitative and quantitative techniques aid in determining the presence and the degree of defects in the MMC joints.

Concluding Remarks

The study of MMC is being carried out aggressively for almost past four decades. However, its wide application in structural components is not widely realized due to inherent challenges in welding and joining them. Among the joining methods, solid state techniques are emerging as potential candidates to join MMCs. Having said that, the conventional fusion welding techniques such as GTAW and GMAW can be used to weld MMCs provided suitable care is taken to avoid detrimental reactions. High energy intensity based techniques such as LBW and EBW have good scope for welding joints with good precision and quality. The heterogeneous joining techniques like soldering and brazing have immense potential for joining the industrial components ranging from tool inserts to electronic packaging. Currently, the joining of AMCs is widely studied but Magnesium based MMC are emerging as alternate to AMC and there is a need to explore the joining options and technologies as magnesium possess its own challenges.

High Performance Machining of Metal Matrix Composites

Keng S Woon, National University of Singapore, Singapore

Introduction

Metal matrix composite (MMC) is a marvel of modern engineering. By reinforcing a base metal alloy with intermetallic compounds in the form of particles, whiskers or continuous filaments, mechanical properties of MMCs like yield strength, tensile strength, fatigue strength, elastic modulus, thermal shock, etc. [Kainer \(2006\)](#) become far more superior than the base alloy alone. Thus, MMCs are now used in a much wider context – from advanced space shuttles, fuel-saving automobiles to cost-effective sports equipment since they were first introduced to the aviation industry half a century ago. Most of these applications aim to promote specific strength and stiffness, high-temperature strengths and wear resistance ([Taya and Arsenault, 1989](#)). But one man's meat is another man's poison. Due to the superior mechanical properties as a whole and localized abrasive nature of the intermetallic reinforcements in MMCs, cutting tools usually degrade rapidly during machining, which indicates drastic reduction in the machinability of MMCs ([Everett and Arsenault, 1991](#)). Many studies in the past focused on the effects of the latter.

According to [Weinert \(1993\)](#), the rapid tool wear on both rake and clearance faces is mainly due to direct abrasion of the reinforcements during chip formation and surface generation and deduced that hardness of reinforcement and relative sliding motion between cutting tools and reinforcements are among the main factors. This was supported by a study on the effects of cutting conditions conducted by [Tomic and Tonnessen \(1992\)](#) where they determined severe flank wear on cutting tools corresponds closely to high cutting speeds due to abrasive wear. High feed rates, on the contrary were found to help in preserving tool life and reducing wear. [Li and Seah \(2001\)](#) described such tool wear mechanism as a combination of two-body and three-body abrasion where tool flank face is plowed by reinforcement particles within the metal matrix as well as those dislodged from the matrix. This theory explains the rapid acceleration in abrasive tool wear when the weight percentage of reinforcement exceeds a critical threshold due to mutual interaction between reinforcement particles that eventually resulted in a catastrophic interference. Other than the effects of volume percentage, [Lane \(1992\)](#) also studied size effects of the reinforcement within MMCs. It was reported that a 27% diametric reduction of particulate reinforcement can lead to a 500% improvement in tool life while a 50% decrease in volume percentage of the reinforcement can only improve tool life by 21%. In a separate study, [Gergman and Jacobson \(1994\)](#) also found fine reinforcements in whisker form cause significantly less abrasive wear on the rake face as compared to the relatively bigger reinforcements in the shape of particulate. They claimed that fine whiskers are fragmented by shearing at the primary deformation zone during chip formation.

Surface generation in machining is carried out with the use of physical cutting tools, with precise and well-defined geometries to remove materials mechanically through the formation of chips. Chips are formed through shearing and plastic deformation when the strength of workpiece materials is overcome by the advancing cutting tools at designated cutting parameters and a new surface is simultaneously generated. Through such a mechanical process, topography of the surface and its quality is governed by the tool conditions. But when wear is developed rapidly on cutting tools, tool geometries are altered correspondingly at the same rate, and over time they become greatly deviated from the original design. As a result, the surface topography and surface quality produced are impaired because drastic alteration in tool geometries changes the mechanics of chip formation and surface generation. With the hard and brittle reinforced inclusions, the resultant surface conditions are even more complex. In the machining of Al/SiC_p 20 wt%, [El-Gallab and Sklad \(1998\)](#) found SiC particles are pulled-out of the surface or experienced interfacial debonding, leaving behind voids and scratches while the remaining ones are fractured through secondary crack initiation by plastic deformation within the metal matrix. The use of average surface roughness (Ra) to describe surface qualities of this sort is less presentative as the voids and scratches are highly localized. [Ge et al. \(2008\)](#) observed an improvement in surface finish with SiC particles are pressed back into the surface through careful control of the cutting process although microstructures on the machined surface are inevitably deformed. The findings were reported following a study using monocrystalline diamond tools on an ultraprecision lathe machine. With similar observations, [Kannan and Kishawy \(2006\)](#) revealed significantly greater hardness closer to machined surface than the subsurface as a result of work-hardening induced plastic deformation. The plastic zone is deeper on softer metal matrix and vice versa, which implies the effects of particle weight/volume fraction and size on the intensity of subsurface deformation.

The selected few studies above represent two decades of intense research to identify the reasons behind low machinability, the causes of tool wear as well as the difficulties to yield admirable surface finish in MMC machining. This article aims to render a pragmatic discussion on the methods and strategies to promote the machining performance of MMC. The first section provides a detailed description of the cutting process where the unique tool wear mechanism in MMC machining that limits tool life, surface finish, productivity and the overall performance is governed by the modes of interaction between the cutting tools and the reinforced particles within the matrix. Once the root cause of the challenge is clarified, a comprehensive 3-part solution for high performance machining of MMCs is proposed namely: tool materials, cutting fluid and vibration-assisted machining. So, in the second section, the types of commercial tool materials that are proven feasible in machining MMCs are examined and detailed as a guidance for decision making in the shop floor. A sub-section on economic factors and justifications is included in view of the

importance of cost effectiveness. After the decision on tool materials is made, the next step is to develop an effective cutting fluid strategy. Therefore, the third section focuses on the evaluation of various cutting fluids and delivery methods with considerations of the peculiar cooling, lubrication and chip breaking requirements. Finally, in the last part, a high-performance machining solution for MMCs using vibration-assisted machining is discussed as it has great advantage to increase productivity, improve surface finish and save energy.

The Cutting Process

A complete description of the mechanism behind MMC machining involves the matrix deformation and interactions between the cutting tool and reinforcement particles. From a statistical possibility viewpoint, the cutting edge of a tool will encounter a reinforcement particle either along, above or below the tool path during machining as shown in Fig. 1. According to Pramanik *et al.* (2007), the contact and deformation mechanics derived from these interactive configurations give rise to tool wear, surface damage and particle debonding during MMC machining.

Consider incremental stages of a typical machining operation of particulate reinforced MMC by means of von Mises strain evolution illustrated in Fig. 2(a)–(f). In the beginning when the tool advances into the MMC workpiece, the matrix is deformed in bulk by the rake face and shearing takes place along the primary deformation zone. Further advancement of the tool will eventually meet a particle at the cutting edge and cause it to debond from the matrix. The hard particle is loose and thus unlikely to be sheared by the cutting edge but as it remains on the machined surface, the flank face of the passing tool will plow against it and induces plastic deformation on the matrix around its vicinity. Eventually the debonded particle is dislocated from the matrix entirely – leaving behind cracks and pit holes on the machined surface due to particles dislocation and plowing as shown in Fig. 3.

Meanwhile, the chip produced simultaneously as the matrix is severely deformed climbs on to the rake face and establishes the secondary shear zone. Through such tribological interactions, particles above the tool path will begin to debond as the chip climbs along the rake face continues to grow in size. Eventually most of the particles that come into direct contact on the rake face are debonded entirely towards the end of the secondary shear zone while some will still be remained in the chip. On the other hand, particles below the tool path do not come into direct contact with the tool and therefore will not be deformed but they are pressed further into the machined surface akin to a micro-indentation process (Pramanik *et al.*, 2006) and resulted in a strained or work-hardened layer in the subsurface of the matrix. Fig. 4 shows the depth of such work-hardened layers in two different aluminum MMCs after machining.

The intermetallic reinforcements used in MMCs be it carbide, oxide or nitride are very hard and highly abrasive. The numerical results in Fig. 2 with excellent microscopic details confirm that the cyclical plow engagement of these reinforcing particles contributes mainly to crater and flank wear development on the cutting edge (Fig. 5(a)). To some greater extent with reinforcement particles that are relatively larger in size and/or weight percentage above some critical threshold, deep grooves or notches (Fig. 5(b)) and intergranular fracture (Fig. 5(c)) on the flank faces are produced. In conjunction with the use of high cutting speeds, the cutting edge can undergo a complete catastrophic fracture (Fig. 5(d)) associated with thermo-mechanical failures. Wear on the rake face caused by two-body and three-body abrasion of the bonded and debonded particles when chip flows on the rake face is notably less severe as a comparison with the absence of cyclical plowing.

Tool Materials

Material removal in machining is performed with the use of physical cutting tools. The three salient attributes in cutting tools that promote durable usages are: (1) high temperature stability; (2) brittle fracture resistance; and (3) surface deformation resistance. The latter governed by the hardness of tool materials is essential in machining MMCs while preventing accelerated abrasive wear by the

Fig. 2 Evolution of tool-particle contact behavior and von Mises strain. Reproduced from Pramanik, A., Zhang, L.C., Arsecularatn, J.A., 2007. An FEM investigation into the behavior of metal matrix composites: Tool-particle interaction during orthogonal cutting. *International Journal of Machine Tools & Manufacture* 47, 1497–1506.

intermetallic reinforcements. Conventional cemented carbides are usually limited to roughing purposes (Teti, 2002) by leveraging on the good balance between toughness and hardness to remove bulk materials without over emphasis on surface quality and dimensional accuracy. This is largely because tungsten carbide grains in cemented carbide tools are not much harder than intermetallic reinforcement particles like silicon carbide and alumina and therefore concentrated loading in finish machining will lead to rapid development of localized tool wear. Diamond coatings attempted in the past (Chou and Liu, 2005; Kremer *et al.*, 2008; Wang *et al.*, 2010) to improve

resistance against abrasion did not gain reasonable success as surface coatings are prone to fail under intense loading. With hardness as the priority, two commercial tool materials can still be considered: (1) polycrystalline diamond (PCD); and (2) cubic boron nitride (CBN).

PCDs are synthetic diamonds reproduced based on mankind's understanding of natural diamonds – the hardest and one of the most valuable materials on earth. Natural diamonds were formed deep underground, up to 700 km from the surface of the earth where pure carbon is crystalized in very strong cubic structures the under optimal conditions of high pressures and high temperatures (HPHT) several millions of years ago. Thus, these precious stones are scarce and too costly for machining operations despite the excellent hardness of up to 10 Mohs (Klein, 2007) is most ideal to resist abrasive wear. This has inspired intense research and by 1955, the first synthetic diamond coined as PCD was produced from graphite by General Electric in USA with an optimized HPHT process. Using a similar method, CBN is synthesized from a polycrystalline mass consists of boron and nitride and the resultant hardness is only superseded by diamonds. CBN has since been used successfully in special machining applications. Primarily, a selected group of materials primarily made up of iron-, nickel-, cobalt-based alloys (Oya and Otani, 1979) that cannot be handled with PCD tools due to chemical solubility at high temperatures. The feasibility of using PCD and CBN for MMC machining was previously validated alongside with conventional tooling like high speed steel (HSS), coated HSS, cemented carbide (WC) and coated WC.

Fig. 6 shows the collective tool life and cutting speed results tested on cast and powder-formed aluminum-based composites reinforced with 20 wt% silicon carbide particles adapted from Hung *et al.* (1995). As tool life is governed by abrasive wear in MMC machining, the performance ranking that goes by hardness differences among tool materials is logically expected. PCD and CBN tools are consistently more superior than other tool materials due to superiority in surface hardness and such superiorities are linearly proportional to hardness as summarized in Table 1. At comparable cutting speeds, PCD tools can outlast coated and uncoated WC tools by two scale order of tool life in minutes and around a scale order compare with CBN tools. HSS tools perform very poorly in machining MMC and therefore should not be considered entirely. It is also worth noting that the usefulness of surface coatings is very limited, be it on WC or HSS the life span of cutting tools will be governed by coating conditions when they are coated. Once coatings are failed by peeling or chipping, the tools can no longer be used because cutting loads generated from the process and particles abrasion will be highly concentrated on the coating failure sites, resulted in accelerated degradation and

then catastrophic fracture. This phenomenon is especially prominent for milling and drilling where cutting is performed intermittently.

Despite the superiority of PCD as depicted in Fig. 6, there is a speed limit in how fast PCD tools are used for MMC machining due to the formation of built-up edge (BUE). High cutting speed generates large amount of heat through friction and shearing during chip formation. A large fraction of the heat is taken by the PCD tools due to the high thermal conductivity of diamonds. The remaining is carried away by the chip and transferred into the workpiece through conduction. At high cutting speeds, the workpiece is readily heated up and resulted in thermal softening of the work materials adjacent to the cutting edge. In the subsequent cycles of cutting, these materials are deposited onto the tools and built up continuously under a combination of enabling localized pressure and temperature. Fig. 7 shows a sample of BUE on PCD tools and its x-ray dispersion profile. Though BUE can reduce abrasive wear on the cutting edge momentarily, it is an unstable two-phase compound that breaks down

Table 1 Hardness of selected tool materials

Material	Knoop hardness (1N, 15 s)
PCD	7000
CBN	3800
SiC	2500
WC	2100
TiN	1770
HSS	980

Fig. 7 Development of built-up edge on PCD tools and its x-ray dispersion profile Reproduced from El-Gallab, M., Sklad, M., 1998. Machining of Al/SiC particulate metal matrix composites Part II: Workpiece surface integrity. *Journal of Materials Processing Technology* 83, 277–385.

unpredictably when its size gets bigger. Through a vicious cycle of building up and breaking down, BUE brings about deterioration in part accuracy and surface finishing and therefore should be prevented in machining.

From the results above, it is noteworthy that metal matrix composites are considered as difficult-to-machine materials (Barnes and Pashby, 1995) due to its highly abrasiveness. Therefore, it is vital for manufacturing engineers to deploy the right type of tool materials to avoid premature tool failure and frequent machine down. But there is a fuller picture to consider when it comes to making this decision – economic factors and justifications of the manufacturing operation. Tool life aside, different tool materials operate at different ranges of speed, feed and depth of cut which determine the material removal rates and productivity of the process. While it is tempting to use PCD and CBN tools for every machining need and scenario, the cost of these tooling may not be economically feasible for the whole operation. A decision on tool materials is thus best made with a mindful balance between cost and productivity.

In the economics of machining, an economy index E can be derived for each tool material as reference based on the type of machining operation, by considering the cost per cutting edge M and the material removal rate Q : $E=M/Q$ (Hung *et al.*, 1995). **Table 2** illustrates the economy indexes for a range of tool materials for a facing operation. Lower E values indicate a more economical process and vice versa. Exploring a cost-effective solution based on the economy index, it is recommended that MMCs should be subjected to rough machining with uncoated WC tools and followed by finishing cut with PCD tools.

Cutting Fluids

Cutting fluid is used in machining as performance-enhancing agents. In general, these fluids are specially designed to serve two primary purposes: (1) remove heat generated from frictional heating and shear heating during chip flow and material deformation; (2) reduce coefficients of friction at tool-chip and tool-work interfaces; and a secondary purpose: (3) facilitate in the breaking of chips into small segments for evacuation and disposal. It is usually supplied directly to the cutting zone, as close to the cutting edge as possible where chip formation takes place. In most scenario, cutting fluids are delivered at high pressure to break and flush the chips away from the cutting zone. When chips are broken down and removed efficiently, the access of cutting fluid to

Table 2 Indicative economy index of selected tool materials in machining MMCs

MMC	Cutting tool	HSS, TiN/HSS	WC	TiN/WC	CBN	PCD
Powder-formed	Cutting speed (m/min)	0.42	3.5		21	55
	Relative speed	1	8.3		50	131
	Economy index (US\$ min/cm ³ /edge)	510	6.9		204	104
Cast	Cutting speed (m/min)		5.5	13	131	572
	Relative speed		13	31	312	1362
	Economy index (US\$ min/cm ³ /edge)		4	5	33	10

the cutting edge is improved so that the intended cooling and lubrication effects are realized. For hole-making operations with restrictive fluid access from the outward, through-spindle systems are used to deliver cutting fluids through internal conduits of the spindles through the drills and then the cutting edges. Therefore, successful application of cutting fluids can help in regulating cutting temperatures and alleviating frictional contact. As a result, thermo-mechanical wear on cutting tools is minimized, tool life is prolonged and machining performance is enhanced, which can be indicated from reductions in cutting force and cutting energy as well as improvements in surface finishing and dimensional accuracy.

Cutting fluids are formulated according to the two primary purposes. For heat removal, water-based cutting fluids with high specific heat and thermal conductivity (Groover, 2017) known as coolants are proven effective. For friction reduction, on the other hand, oil-based cutting fluids or lubricants that form lubricating thin-films at the tool-chip and tool-work interfaces are used. Coolants are applied in machining processes and applications such as turning and milling of stainless steels that require high cutting speeds or when thermally vulnerable tool materials such as high speed steel or uncoated cemented carbide are in use. Under these conditions where aggressive heat generation or severe thermal damage is inevitable, the use of coolant helps to remove intense heat from cutting tools and workpieces through conduction so that cutting temperatures are kept at operational safe, and non-alarming levels. On the contrary, lubricants are usually used in low cutting speed applications like broaching, tapping or drilling. These oil-based cutting fluids are formulated with extreme pressure (EP) additives like organic sulfur, phosphorous or chlorine compounds, which chemically establish thin films on the cutting tools under high, localized pressures at the contact interfaces. These thin films with thicknesses ranging in the micrometer and nanometer scales are maintained on cutting tools at low cutting speeds and keep them from continuous direct contact with chips and workpieces. Through this mechanism, the lubricated cutting tools are subjected to lesser friction and hence mechanical abrasion and frictional heating are also reduced correspondingly.

Commercial cutting fluids are typically classified in 3 categories: (1) cutting oils; (2) emulsions; and (3) synthetic/semisynthetic fluids. Cutting oils are developed from petroleum, animal, vegetable, and fish in conjunction with a careful blend of EP additives, oxidation inhibitors, rust preventatives, antiseptics, odor control agents and anti-foaming agents (Groover, 2017). Cutting oils have superior lubricating properties due to their strong adhesion on metallic surfaces as well as their high viscosities, which allow the formation of effective thin-films with large thicknesses compare with those of water-based fluids. As a result, the impact of frictional contact during machining is greatly minimized. But thermal conductivity and specific heat of cutting oils are relatively low and thus the capability to cool is weak. To improve cooling capabilities in cutting fluids, water being one of the best cooling medium is essential. For applications that call for both effective cooling and lubrication, mineral oils blended in water known as emulsions or emulsifiable oils can be considered. Emulsions combine mineral oils in water at designated proportions and stabilized with emulsifying agents to disintegrate oils into droplets alongside with EP additives to enhance the lubricating effects under high localized pressures. Commercial emulsions are custom made from mixing 1–5 parts of emulsifiable oil in 100 parts of water (Fiytzpatrick and Smith, 2019) to cater for varying levels of cooling and lubrication requirements in an application. To maximize cooling effects, synthetic fluids that are 100% water-based and chemically enhanced with inorganic chemicals including blending agents, rust prevention agents and anti-bacteria agents are used. Certain EP additives like phosphorous, chlorine and sulfur compounds are also incorporated to promote some levels of lubrication and friction reduction. If more lubrication properties are desirable, small amount of emulsifiable oils are added into synthetic fluids. These cutting fluids are marketed as semisynthetic fluids. On top of these conventional options, the use of liquid nitrogen as cutting fluid to improve tool life and machining performance has been an on-going research (Shokrani et al., 2012).

Consider a comprehensive feasibility study (Duan et al., 2019) on the cooling and lubrication effectiveness of different cutting fluids and supply conditions: (1) Oil: Flooding neat cutting oil at 36 l/h; (2) Emulsion: Flooding a blend of oil to water ratio 1:10 at 36 l/h; (3) MQL: Minimum quantity lubrication is delivered as mist with a mixture of oil and pressurized gas at 0.4 MPa that consumes oil at 83 ml/h; (4) LN₂: Liquid nitrogen with a calibration temperature of –165°C and delivered at 0.4 MPa. (5) Dry: Machining is performed without cutting fluids. Silicon carbide particle reinforced aluminum matrix composites (Al/SiC_p 50 wt%) are subjected to turning with PCD tools at a cutting speed 120 m/min, feed rate 0.1 mm/rev and depth of cut 0.2 mm for a uniform distance of 1375 m. Synthetic fluids are not used in the study as the tool wear mechanism is mainly driven by frictional contact of the particle reinforcements. Abrasive wear is a direct product of such wear mechanism due to mechanical abrasion while

Fig. 8 Built-up edges and adhesive materials found on rake faces except emulsion application. Reproduced from Duan, C., Sun, W., Che, M., Yin, W., 2019. Effects of cooling and lubrication conditions on tool wear in turning of Al/SiCp composite. *The International Journal of Advanced Manufacturing Technology* 103 (1–4), 1467–1479.

subsequent sliding contact heats up both cutting tool and workpiece. When the heated surfaces come into contact, thermally softened workpiece is adhered on cutting tools under high localized pressures and form unstable build-up edges (BUEs) over the cutting edges. As cutting goes on, BUE continues to grow in size until a saturated stage is reached where it will be detached either partially or entirely from the cutting tool and leave a tear mark behind known as adhesive wear. As shown in **Fig. 8**, the study found BUEs and traces of adhesive wear for all cutting with MQL, LN₂, Oil except Emulsion. This implies neither extreme cooling nor lubrication, but a balance between the two can suppress the formation of BUEs and prevent adhesive wear in MMC machining.

Fig. 9 shows the flank wear (VC) at different stages of the same feasibility study. As discussed previously in Section “The Cutting Process”, flank wear in MMC machining is mainly caused by mechanical abrasion of the reinforced particle. From the results (Duan *et al.*, 2019), the best flank wear performance was achieved under LN₂ and MQL conditions while on the contrary, the used of emulsion and neat cutting oil produced the worst. It is believed that the highly tight contact established between flank face and workpiece during machining restricts the access of unbonded particles. Therefore, the use of flooding methods to deliver emulsion and oil to the cutting edge for flushing and evacuation of loose particles does not produce visible improvements. Worse still, supplying cutting fluids to the tools that are already heated up through frictional heating and plastic deformation leads to formation of vapor pockets around the tool, which restricts the access of lubricant and thus resulted in severe abrasive wear. The use of LN₂ and MQL has the advantage to eradicate these vapors with the pressurized gas while delivering the cooling and lubricating agents to the narrow flank face zone that improves the frictional conditions and greatly reduces flank wear on cutting tools. Such findings also imply flank wear on cutting tools is primarily induced by 2-body abrasion in MMC machining.

Vibration-Assisted Machining

The challenges in optimizing MMC machining performance is directly related to the challenges in managing wear rate of cutting tools (Muthukrishnan and Davim, 2009). These challenges originate from the on-going interaction between the cutting tools and abrasive particles in MMCs. Unbonded particles trapped between the rake face and the chip bottom coupled with bonded particles in the chips induce severe crater wear on rake face through a complex 3-body abrasion action. Crater wear is aggravated by MMCs with higher weight percentage of reinforced particles in the matrix (Joshi *et al.*, 1999). On the other hand, wear on the flank face is primarily caused by 2-body abrasion of bonded particles on the machined surface after the immediate layer of materials is removed. Such wear on flank face usually deteriorates with intensification in springback or elastic recovery (Quan and Zhou, 2000) by making wrong choices on machining conditions or tool materials. Moreover, applying the right cutting fluids with the right method can suppress wear development on both faces by providing the necessary cooling and lubrication. Otherwise, the use of cutting fluids is counterproductive and a waste of resources.

The central issue of effective cutting fluids application in MMC machining is accessibility. During chip formation, the part of rake face adjacent to the cutting edge is always tightly engaged at the chip root while the remaining is constantly shielded by the forming chip. Similarly, the flank face adjacent to the cutting edge is always adhering against the machined surface despite having a back-grinding clearance angle, owing to the finite tool sharpness. Under these contact conditions, the access to the rake and flank faces by cutting fluids is therefore highly restrictive. To overcome this major issue, cutting tools should be displaced to create enough clearance for cutting fluids to infiltrate both tool faces. If such tool displacement is precisely executed, even if it's just momentarily, the rate of tool wear development can be improved when tool wear is alleviated to a certain degree by instant cooling and lubrication, through successful cutting fluid infiltration. In addition, by displacing the tools disrupt continuous 2-body abrasion on both rake and flank faces and minimize 3-body abrasion on the former by relieving unbonded particles trapped in between chips and rake faces. Once the desirable outcomes are achieved, restore the tools back to the original paths and positions to continue with the intended cutting. By repeating such tool displacement and restoration interchangeably, systematically and at a high level of accuracy, high performance machining of MMCs is readily realized. The feasible machining technology to deliver such peculiar requirements is vibration-assisted machining (VAM).

VAM was originally developed to machine difficult-to-machine materials like ceramics (Weber *et al.*, 1984), steel (Moriwaki and Shamoto, 1991), and glass (Moriwaki *et al.*, 1992). Traditionally, hard and brittle materials and iron-based alloys were not

Fig. 9 Flank wear variations with cutting lengths under different cooling and lubrications conditions. Reproduced from Duan, C., Sun, W., Che, M., Yin, W., 2019. Effects of cooling and lubrication conditions on tool wear in turning of Al/SiCp composite. *The International Journal of Advanced Manufacturing Technology* 103 (1–4), 1467–1479.

machined cost effectively with conventional machining technologies. Through the induction of low-amplitude and high-frequency vibration at the cutting edge, these materials can be machined successfully with better surface finishing, improved dimensional accuracy, lower cutting force, prolonged tool life, and increased in productivity. Coupled with the right machining parameters, VAM has been proven reliable to produce crack-free functional surfaces on hard and brittle materials known as ductile-mode machining (Pei and Ferreira, 1998) by facilitating material removal at a special range of undeformed chip thickness. Also, diamond tools that were not previously used in machining iron-based alloys due to the vulnerability of diamonds with the presence of iron under elevated temperatures and pressures has since been successfully revolutionized by using VAM. Through periodical displacement of the cutting tools, heat is unable to build up continuously on the affected zones to reach the necessary temperatures for the onset of graphitization.

Such capable VAM systems are divided based on the number of cutting axis: (1) 1-dimensional; and (2) 2-dimensional where either a linear reciprocating motion or a repetitive bi-axial motion in ellipse are involved. Fig. 10 depicts a 1-D VAM system that typically consists an ultrasonic transducer, sonotrode, and cutting tool mounted on a base plate. According to Brehl and Dow (2008), chips are produced by the cutting tool that is periodically displaced from the workpiece when the linear vibrating frequency is superimposed with the upfeed velocity of workpiece as shown in Fig. 10. On the other hand, a 2-D VAM uses a more complex system based mainly on a 4-piezoelectric actuators control, where each pair governs motions in the vertical and horizontal axes respectively as shown in Fig. 11. Sinusoidal voltage is separately applied to the upper-lower pair and the front-back pair to generate mutually exclusive vibrations in the cutting axis and the axis perpendicular to the cutting axis (Shamoto et al., 2002). With proper regulation of the bi-axial resonance, useful elliptical vibration is generated, and material removal is carried out by diamond tools at the tip of the module. As the tools vibrate elliptically along the main cutting direction, chips are intermittently formed when the tools are brought towards the workpiece while the newly formed chips are seemingly extracted when the tools are brought away from the workpiece. This process as shown in Fig. 11 is cyclically repeated throughout the process. Such cutting action is believed to improve tribological properties, which are beneficial to improve tool wear and surface finish (Xing et al., 2013).

To demonstrate the effectiveness of 1-D VAM in reducing cutting forces, Fig. 12 shows force distributions when Al/SiCp 25 wt% is subjected to turning with PCD tools under vibration-assisted mode and conventional turning (CT) without vibration-assisted as reported by Bai et al. (2019). Continuous material removal was performed without vibration-assisted for a duration of 40 s, which started from preliminary tool engagement at 20-s to 60-s. Then the mode of machining was switched to the vibration-assisted from the 60-sec mark, lasted for another 40 s before disengaging the cutting tool from the workpiece. By introducing ultrasonic vibrations to conventional machining on the same setup while keeping the rest of cutting conditions and parameters entirely constant, the cutting force produced is found to reduce drastically by an approximation of 58%. Reduction in cutting force is of great practical importance since it is a principal component in the functions of cutting energy and thus a reduction in cutting force also implies a corresponding reduction in cutting energy by scale. Aside from primary cutting force, such linear reciprocating motion also led to reductions in feed and thrust force in smaller scales that are positive indicators of a more sustainable process in general.

On top of cutting force, the advantages of VAM can also be observed from the type of chips produced. Fig. 13 illustrates the chips produced by VAM and CT under the same machining conditions in Bai et al. (2019). With vibration-assisted, CT produces 'short C-type' chips that are highly fragmented compare to the long, continuous 'spring-type' chips produced by VAM. The former presents saw-tooth like features on the free surface and multiple fractures on the back surface, which indicate adiabatic shearing

and random segmentation during chip formation. In contrast, the latter has a continuous, uniform lamella structures on the free surface with little or no fractures on the back surface which in turn, implies a stable history of plastic deformation. The findings are largely due to the tendency of reinforced particles in MMCs to accumulate in the primary deformation zone during chip formation in CT. Chips break into fragments randomly when particles accumulation intensifies, leading to the formation of unstable pile-ups. This explains the distinctively different features and morphology in chips produced with VAM as the vibrating motion at designated ultrasonic frequency has the capability to redistribute reinforced particles from the primary deformation zone back to the matrix and avoid random segmentation of chips due to active particles pile-up.

Fig. 13 Different chip types and morphologies produced with (a) conventional turning; and (b) vibration-assisted machining. Reproduced from Bai, W., Roy, A., Sun, R., Silberschmidt, V.V., 2019. Enhanced machinability of SiC-reinforced metal-matrix composite with hybrid turning. *Journal of Materials Processing Technology* 268, 149–161.

From the scale of force reduction to the distinctive chip morphology produced through VAM and CT, the resultant surface topography and quality as shown in Figs. 14 and 15 also differ correspondingly (Bai *et al.*, 2019). Fine, longitudinal grooves are found along the cutting direction on both types of surfaces. These grooves are formed during chip formation when the reinforced particles that accumulate at the primary deformation zone are driven passively by the cutting tool to plow on the machined surface along the tool path. Amid the particle-plowing process under CT, some of the particles tend to unbind and detach from the machined surface that leaves tear-like pitted defects along the longitudinal grooves. Such surface defects are shown in Fig. 14. On the contrary, such pitted defects are not found on machined surfaces produced under vibration-assisted mode as shown in Fig. 15. Particles unbounding is more prone to happen in CT when the particles of different size and at varying depths related to the cutting path are held in chips with uniform thicknesses. This is followed by a secondary detachment from the holding chip leads to the production of highly fragmented chips. These undesirable phenomena can be resolved by introducing ultrasonic vibration motion to machining, which yields long, unfragmented chips with varying thicknesses although the grooves generated on the surface are slightly deeper due to the amplitude of vibration. Improvements in surface roughness up to 15% has been achieved.

Conclusions and Future Outlook

Machining of metal matrix composites (MMCs) is challenging. This article describes the fundamentals behind the challenge, largely attributed to the hard and brittle reinforced particles within the composites that also contribute to the superiority of MMCs in terms of mechanical properties. Since machining relies on the use of solid cutting tools to generate shapes and features, physical interaction between the particles and cutting tools leads to severe abrasive wear, which impairs the effectiveness of chip formation and undermines the overall performance of the machining process. The following conclusions are thus drawn from the present article:

- (1) Polycrystalline diamond (PCD) is the most ideal tool material for MMC machining for its ultimate hardness to resist mechanical abrasion on the surface.
- (2) Combination of uncoated cemented carbide tools for roughing and PCD tools for finishing is the best tooling solution based on pragmatism and cost-effectiveness.
- (3) Emulsions among commercial cutting fluids are best suited for MMC machining to address the equal needs for cooling and lubrication to suppress adhesion.

Fig. 14 Defective machined surface produced with conventional turning. Reproduced from Bai, W., Roy, A., Sun, R., Silberschmidt, V.V., 2019. Enhanced machinability of SiC-reinforced metal-matrix composite with hybrid turning. *Journal of Materials Processing Technology* 268, 149–161.

Fig. 15 Machined surface with improved finishing with vibration-assisted machining. Reproduced from Bai, W., Roy, A., Sun, R., Silberschmidt, V.V., 2019. Enhanced machinability of SiC-reinforced metal-matrix composite with hybrid turning. *Journal of Materials Processing Technology* 268, 149–161.

- (4) Supply cutting fluids in minimum quantity with the use of pressurized gas assures efficient delivery through narrow gaps on to the rake and flank faces.
- (5) Vibration-assisted machining (VAM) of MMCs prolongs tool life by disrupting the wear mechanism through periodic tool separation from workpiece.
- (6) VAM that separates cutting tools from workpiece increases cutting fluids accessibility to tool faces, leading to improved tool wear and machining performance.

Based on these findings, the most direct approach to improve the quality and performance in machining MMC is by reducing tool wear and diminishing its impact. Both of which can be readily benefited from robust tool materials, effective cutting fluids application and reduced exposure to harmful abrasion. The future direction of MMC machining research should thus be converging towards the above-stated conclusions.

Introduction

The demand for technological advancement is gradually increasing for the ease of potential applications in various sectors, which comprise of science, engineering, and biomedical industries. An engineering sector can be broadly classified into manufacturing, automobile, aerospace, marine, and defense. The composite is the combination of different materials that have dissimilar physical and chemical structures. These materials which are combined to form the composite are known as the constituent materials. The constituent materials can be metals, non-metals, organics, or in-organic materials. The composite materials are categorized into three types based on matrix materials, which are polymer matrix composites (PMCs), ceramic matrix composites (CMCs), and metal matrix composites (MMCs). The composite material, which consists of a metal matrix combining with another hard reinforcement, is known as MMCs (Haghshenas, 2016; Trinh and Sastry, 2016; Vijaya Ramnath and Elanchezhian, 2013; Moonaa *et al.*, 2018). Nowadays, various types of materials are in the developing phase to incline with the properties and applications in demand. The researchers are gaining tremendous interest in the composite materials amongst the other materials. The reasons behind the development of the composite materials are due to their excellent mechanical, physical, chemical, and thermal properties, which develop due to the combinations of different materials (Haghshenas, 2016; Mavhungu, 2017; Dasgupta, 2012; Stojanovic and Ivanovic, 2015). The composite material consists of metal as a matrix material, and a doping material, i.e., reinforcement, for improving its properties. The MMCs utilize the matrix material and the reinforcements for obtaining high strength, stiffness, ductility, wear resistance, creep resistance, fatigue resistance, toughness, and corrosion resistance (Haghshenas, 2016; Dasgupta, 2012; Hunt and Miracle, 2001; Prasad and Asthana, 2001; Pai *et al.*, 2004; Allison and Cole, 1993). The cost, performance, and properties of the MMCs depend on the production technique and the type or volume fraction of the material used for reinforcement (ceramic). Matrix materials in the MMCs are either pure metals or alloys. The different types of matrix materials usually used in the MMCs are stated as follows (Trinh and Sastry, 2016; Pai *et al.*, 2004; Allison and Cole, 1993; Kevorkijan, 1999; Rohatgi *et al.*, 2006; Bechmann *et al.*, 2007; Miracle, 2005; Rajak *et al.*, 2020; Rajak *et al.*, 2019), (1) aluminum, (2) copper, (3) magnesium, (4) titanium, (5) nickel and (6) iron. The reinforcement material is the material that improves the properties of the MMCs, usually the strength and/or stiffness. The most frequently used reinforcement materials are ceramics (nitrides, carbides, oxides, etc.). The examples of reinforcements for some MMCs are SiC, Al₂O₃, TiB₂, B₄C, and graphite. The MMCs are classified according to the type and geometric characteristics of the reinforcement materials as shown in Fig. 1.

The selection of suitable reinforcement material depends upon the type of applications, compatibility, and interfacial resistance between the matrix and reinforcement material (Trinh and Sastry, 2016). Continuous reinforcement results in the improvement of properties like wear resistance, thermal expansion coefficient, and thermal conductivity. Discontinuous reinforcement has positive effects on hardness, fatigue resistance, wear-resistance, and dimensional stability. It also results in better stiffness but at the cost of low ductility and fracture toughness (Trinh and Sastry, 2016; Rajak *et al.*, 2019; Elmarakbi, 2014; Miyamoto, 2013; Rashad *et al.*, 2015; Mustafa and Abdulgadir, 2017; Holley, 2013; Peng, 2005; Guo and Derby, 1995; Hayat *et al.*, 2019; Singerman and Jeffrey, 1998; Welsch *et al.*, 1993; Leyens and Peters, 2003). Fig. 2 shows the schematic diagram of the structure of different kinds of MMCs with respect to reinforcement materials.

Properties of MMCs

The MMCs possess a variety of applications, due to their typical properties viz. (1) elevated temperature capabilities, (2) higher radiation resistance, (3) higher transverse strength and stiffness, (4) least moisture absorption, (5) high thermal and electrical conductivity, (6) higher Young's modulus, (7) higher fatigue strength (at elevated temperatures), (8) low density, and (9) high wear and corrosion resistance (Haghshenas, 2016). Along with these advantages in properties, the few drawbacks are (1) expensive production systems; (2) technology is still under developing stage as compared to others, (3) complexity in the manufacturing (especially in case of the long fiber MMCs).

Classification of MMCs

The main categories were explained in the section above. The following are possible sub-combinations of reinforcement material with respect to matrix material:

- Aluminum-based MMCs
 - Long fiber: alumina, silicon carbide, boron, graphite
 - Short fiber: alumina, alumina-silicon
 - Whiskers: silicon carbide
 - Particle: silicon carbide, boron carbide

Fig. 1 Reinforcement based MMCs. Reproduced from Trinh, S.N., Sastry, S., 2016. Processing and properties of metal matrix composites. Mechanical Engineering and Materials Science Independent Study, 10.

Fig. 2 Structure of MMCs based on reinforcement. Reproduced from Trinh, S.N., Sastry, S., 2016. Processing and properties of metal matrix composites. Mechanical Engineering and Materials Science Independent Study, 10.

- Magnesium-based MMCs
 - Long fiber: alumina, graphite
 - Whiskers: silicon carbide
 - Particle: silicon carbide, boron carbide
- Titanium-based MMCs
 - Long fiber: silicon carbide
 - Particle: titanium carbide
- Copper-based MMCs
 - Long fiber: silicon carbide, graphite
 - Particle: titanium carbide, silicon carbide, boron carbide
 - Filament: niobium-titanium
- Super alloys based MMCs
 - Filament: tungsten

Aluminum-Metal Matrix Composites (AMMCs)

The aluminum alloys have excellent thermal conductivity and lower weight, because of which they have numerous applications in the field of automobile, aerospace, and mineral processing (Dasgupta, 2012; Leyens and Peters, 2003; Li *et al.*, 2013; Air Force Technology, 1997; Specialty Materials, Inc.; Liu *et al.*, 2006). It has been discovered that the use of lightweight material with suitable strength has become a priority for researchers (Trinh and Sastry, 2016; Moonaa *et al.*, 2018; Singerman *et al.*, 1996; Connell, 1973; Anderson, 1998; Salvo and Mangalaraja, 2018; Franczak and Karwan-Baczewska, 2017; Rao, 2017; Rajkovic *et al.*, 2010; Hong, 2011; Shehata, 2009; Moghadam, 2015; Lu, 2004; Duarte and Ferreira, 2016). Modern cars are equipped with large screens, electronic amenities, multimedia gadgets etc (Vijaya Ramnath and Elanchezhian, 2013; Leyens and Peters, 2003). This also results in additional weight to the vehicle, which results in increased fuel consumption and environmental pollution. For providing the counterweight to the excess weight added, the aluminum-based MMCs were targeted. Fig. 3 shows the micro-structure of aluminum-based MMCs, with SiC particle distributions in the matrix.

The need for obtaining different MMCs based on Al is gaining significant interest and attention from the researchers. These AMMCs contain a variety of improved qualities. These include better strength to weight ratio, higher strength, high elastic modulus, good ductility, excellent resistance to wear, lower coefficient of thermal expansion, excellent corrosion resistance, high temperature creep resistance and fatigue strength. The reinforcements and the processing methods are majorly responsible for the improved properties in AMMCs (Vijaya Ramnath and Elanchezhian, 2013). The recently used reinforcement materials are mostly ceramics (Al_2O_3 , SiC, MgO and B_4C). The properties of these reinforcement materials like refractoriness, high compressive

Fig. 3 SiC-particle reinforced aluminum-matrix composite material (D.K. Rajak ©).

Table 1 Properties of Aluminum-based MMCs

Properties	Matrix Metal (1)*	Particulate MMCs (2)*	Fiber MMCs (3)*
Strength (MPa) (axial)	290	290–489	620–1240
Stiffness (GPa) (axial)	70	290–480	130–450
Transverse strength (MPa)	290	290–140	30–170
Transverse stiffness (GPa)	70	80–140	34–173
Plane strain fracture toughness (MPa-m)	18–35	12–35	–

Where, (1)* 6061-aluminum, (2)* 6061-aluminum reinforced with 0%–40% of SiC particulate by volume, (3)* 6061-aluminum 50% reinforced with fibers of SiC, graphite, boron, and alumina by volume.

Note: Trinh, S.N., Sastry, S., 2016. Processing and properties of metal matrix composites. Mechanical Engineering and Materials Science Independent Study, 10.

strength, hardness, wear resistance, etc., make them superior to the other reinforcement materials (Moonaa *et al.*, 2018; Dasgupta, 2012; Tjong, 2013; Geim and Novoselov, 2007; Ramkumar, 2018; Mikula *et al.*, 2015; Rawal, 2001; Collins and Mikko, 2000).

Properties of AMMCs

- High strength
- High stiffness
- Reduced density (weight)
- Improved creep resistance at high temperatures
- Moderate coefficient of thermal expansion
- Improved electrical conductivity
- Improved abrasion and wear resistance
- Controlled weight
- Moderate toughness
- Moderate ductility (depends on reinforcement type)

Some essential mechanical properties of the matrix material, particle, and fiber in a comparative way are shown in Table 1. Following categories of AMMCs are:

- Silicon carbide reinforced
- Aluminum oxide reinforced
- Boron carbide reinforced
- Fiber reinforced
- Zircon reinforced
- Fly ash reinforced

Applications of AMMCs

More than 50% of the production of MMCs has applications in the automotive industry. The MMCs are used in modern cars, due to their expensive processing techniques. The applications of AMMCs are demonstrated in brief in the following section (Hunt and Miracle, 2001; Miyamoto, 2013). **Table 2** depicts the applications of aluminum-based MMCs with respect to the manufacturer, composite material, and components in a comparative pattern (Stojanovic and Ivanovic, 2015).

Engine pistons

Engine pistons work under extremely harsh mechanical, dynamical, and thermal conditions. The piston undergoes the cyclic mechanical loading with a frequency of around 100 Hz (Stojanovic and Ivanovic, 2015). Thus, the provision for fatigue strength is primarily important. During the expansion periods, the piston must provide intimate contact with the cylinder under maximal pressures to avoid the pressure drop. The pressure drops lead to astonishing power loss. It is also requisite for the piston to operate at a temperature of around 3000°C (Stojanovic and Ivanovic, 2015), which is generated in the engine while working for a long time. This temperature variation causes thermal impacts, which can be avoided by providing high thermal conductivity. **Fig. 4** shows the actual sectional view of a piston produced with AMMCs.

In 1983, a reputed Japanese automobile manufacturer named Toyota car manufacturer started the production of pistons for diesel engines. The material used for the production was AMMC, which proved to be a breakthrough in applications (Hunt and Miracle, 2001; Miyamoto, 2013). Those composites were produced by the squeeze casting technique (SCT), which resulted in large

Table 2 Some of the Al matrix composite applications along with the manufacturers

<i>Manufacturer</i>	<i>Composite</i>	<i>Component</i>
Duralcan, Martin marietta, Lanxide	Al/SiCp	Pistons
Duralcan, Lanxide	Al/SiCp	Calipers, Brake rotors, Liners
GKN, Duralcan	Al/SiCp	Propeller shaft
Nissan	Al/SiCw	Connecting rod
Dow chemical	Mg/SiCp	Pulleys, Sprockets
Toyota	Al/Al ₂ O ₃	Piston rings, Al/Boriaw and saffil
Dupont, Chrysler	Al/Al ₂ O ₃	Connecting rods
Hitachi	Cu/Graphite	Current collectors
Martin Marietta	Al/TiCp	Pistons, Connecting rods
Honda	Al/Al ₂ O ₃ – Cf	Engine blocks
Lotus Elise, Volkswagen	Al/SiCp	Brake rotors
Chrysler	Al/SiCp	Brake rotors
GM	Al/SiCp	Engine cradle, rear brake drum for EV-1, driveshaft
MC – 21, Dia-Compe, Manitou	Al/SiCp	Disk brake rotors, bicycle fork brace
3M	Al/Nextelf	Missile fins, aircraft electrical AC door
Kobenhavn, Knorr-Bremse	Sic/Al	Brake disk on ICE bogies
Alcoa Innometalx	Al/SiCp	Multichip electronic module
Lanxide	Al/SiCp	PCB heat sinks
Cercast	Al/Graphite foam	Electronics packages
Textron Specialty Materials	Al/B	PCB heat sinks

Fig. 4 Pistons made of AMMCs. Reproduced from Stojanovic, B., Ivanovic, L., 2015. Application of aluminum hybrid composites in automotive industry. Tehnicki Vjesnik 22 (1), 247–251.

scale production of over 1,00,000 items per mount. This production rate resulted in excellent quality at satisfactory costs. The ceramic reinforcements in the MMCs used for producing the pistons had higher wear resistance as compared to the matrix material (Stojanovic and Ivanovic, 2015). Simultaneously, pistons possessing lower values of thermal expansion coefficient result in the provision of narrow tolerances. The requirement of narrow tolerances provides an increase in maximum pressures allowed and thus improved thermal properties. Besides that, the method of piston fabrication and the casting of MMCs are quite similar (Hunt and Miracle, 2001). The price of aluminum material is high, but the cost of pistons is comparatively lower than the pistons produced using traditional materials. Silicon carbide (SiC) is usually used as the reinforcement material in the MMCs used in race cars. The Asian and western European car producers heavily use pistons made of MMCs (Stojanovic and Ivanovic, 2015).

Engine cylinders

Substantial use of aluminum alloys for the production of the engine block led AMMC to find its application in manufacturing engine cylinders. In 1990, mass production of the cylinder barrel made of AMMC had emerged. In the beginning, AMMC was used in 2.3 L of Honda Prelude engine, which was made of aluminum matrix hybrid composite material with reinforcement of carbon and Al_2O_3 (Hunt and Miracle, 2001). The production process used for cylinder barrel was squeeze casting at moderate pressure. Fig. 5 shows the sectional view of the engine block cylinder barrel (EBCB) of Honda Prelude produced with AMMCs.

AMMC shows higher resistance to wear than that of cast iron (Stojanovic and Ivanovic, 2015). By application of AMMCs, the overall engine block weight is reduced by 20%. Also, the increase in work volume was achieved without redesigning due to the thickness of the cylinder barrel, which was lesser than the one made from cast iron. The engines with cylinder barrel made of AMMCs are efficiently deployed in Honda S2000 sports cars, Acura NSX cars, and Porsche Boxster Motors. The engines of Toyota Celica 2000 series cars also consist of cylinder barrels made of AMMCs (Stojanovic and Ivanovic, 2015). AMMC made cylinder barrels are used in high-performance Honda Motorbikes.

Engine pushrods

Fiber reinforced AMMCs are used for the production of valve pushrods in engines. The matrix used is an aluminum alloy, while fibers of Al_2O_3 are used as the reinforcing material. 3M Corporation initially started the production of parts made of AMMCs. AMMC made pushrods showed 25% higher stiffness and twice the shock absorption capacity than the parts made of standard steel. Also, the exploitation period of AMMC made pushrods is also exceptionally higher than the ones produced with steel. The engine pushrods produced with AMMCs are shown in Fig. 6. Rotations per minute (rpm) can be increased to 200–400 without the addition of dynamic loads, due to lesser density and weight.

Engine connecting rod

By producing the connecting rod (see Fig. 7) with AMMCs, the mass reduction of 57% can be achieved as compared to the steel ones. The mass reduction of the piston or connecting rod results in the reduction of vibration during operation. This results in many positive effects, such as lessen the load on the crankshaft and bearings, energy losses due to friction and fuel consumption. It is discovered that the decrease in 1 kg of mass in crankshaft results in a reduction of 7 kg of mass in balancing counterweight. The connecting rods produced with the reinforcement of SiC and Al_2O_3 are deployed by Nissan and Dupont/Chrysler, respectively (Miracle, 2005). The implementation of AMMC for the production of the connecting rods results in lesser fuel consumption with the improvement of engine power, but, simultaneously, there is an increase in the total production cost (Prasad and Asthana, 2001). Furthermore, the researchers of MMCs are making some rapid approaches for producing different materials used in making the engine connecting rods (Kevorkian, 1999), and the research in this field is still in progress.

Brake systems

Disks and drums in a braking system of vehicle are being produced by AMMCs due to their beneficial properties like high wear resistance and high thermal conductivity. **Fig. 8** shows the components of the brake system which use the AMMCs as the parent material. There is a significant reduction in inertia forces, net weight, and fuel consumption, due to a decrease in the weight of material deployed. Brake disks and drums are manufactured by Al-Mg and Al-Si alloy materials reinforced with ceramic materials (such as SiC, Al_2O_3). With the volumetric share of 20% reinforcing materials in the AMMCs, the production processes use unique casting methods. A large number of producers are now using AMMCs for the production of brake systems in the automotive industry.

At Lotus Elise (1996–1998), and Plymouth Prowler uses a rear set of brakes system produced with AMMCs. Discontinuous reinforced AMMCs is used in disk brakes of Volkswagen Lupo 3L and Audi A2. Hybrid and electrical vehicles, such as Toyota RAV4, Ford Prodigy, and General Motors Precept are also equipped by the brake systems produced with AMMCs (Hunt and Miracle, 2001). The high-speed train in Germany, InterCity Express (ICE), also uses the discontinuous reinforced AMMC brake disks (Hunt and Miracle, 2001). Braking pads produced with AMMCs are also deployed in Porsche 911 series. All of these composites consist of ceramic reinforcements.

Propeller shaft

For the manufacturing of propeller shafts, AMMCs are deployed due to their high specific stiffness. The major drawback of the new propeller shaft is its critical rotational speed, which makes it dynamically unstable. The shaft length, its internal and external diameter, and the specific stiffness decide the critical rotational speed of the shaft (Stojanovic and Ivanovic, 2015). Deployment of propeller shaft with AMMCs provides flexibility over designs, for example, increasing the shaft length while keeping the diameter constant or decreasing the shaft diameter while keeping the length constant. Structural weight reductions are obtained at such dimensions, which provide beneficial possibilities for alternative design solutions. Reinforcement of ceramic material, Al_2O_3 , with

a matrix of Al 6061 is deployed using the stir casting production process. At the beginning of 1997, propeller shafts made of Al_2O_3 -Al 6061 composite were first applied in Chevrolet S-10 and GMC Sonnomo delivery truck. Propeller shafts made from AMMCs were also used in the Chevrolet Corvette and Ford Crown Victoria, which is shown in [Fig. 9](#).

Other applications in automobile

Brake caliper assemblies, turbine blade, gear pairs, turbo-compressors, belt pulleys, valves, pump housings, and supporting parts are also getting manufactured by AMMCs due to their material properties and specific characteristics. Higher wear resistance, lower coefficient of thermal expansion with improved thermal properties are some potential advantages provided by the AMMCs for the production of machine parts. AMMC prices are reducing with the trend of an increasing quantity of produced parts; otherwise, prices are still high ([Stojanovic and Ivanovic, 2015](#)). The AMMCs also have potential applications in the electronic packaging industry, which is represented in [Fig. 10](#).

Magnesium-Metal Matrix Composite (MMC)

MMCs based on magnesium alloys such as Mg-Al are in demand nowadays as it serves the market need of a lightweight, high-performance materials for civic, military, and aerospace applications ([Mustafa and Abdulgadir, 2017](#)). MMCs are also showing conceivable applications in the automotive industry, such as gears, gearbox bearings, disk rotors, piston ring grooves, connecting rods, and shift forks. One of the drawbacks of magnesium-based MMC is higher production costs due to their complex manufacturing processes. Growing demands of high-performance magnesium MMC materials incites researchers to develop a diverse range of reinforcement materials with advanced composite manufacturing techniques. Magnesium-based MMCs, when reinforced with continuous carbon fibers, showed 1000 MPa bending strength with a material density of 1.8 g/cm^3 . The condescending mechanical properties can be retained at elevated temperatures

Fig. 10 Discontinuous reinforced aluminum MMCs for electronic packaging applications. Reproduced from Rawal, S., 2001. JOM 53 (4), 14–17.

Table 3 Comparison of pure Mg and (Mg/0.3 wt% GNPs) composite mechanical properties

Materials	Elastic Modulus (GPa)	0.2% Yield Strength (YS) (MPa)	Ultimate Tensile Strength (MPa)	Strain Failure (%)	Vickers Hardness (HV)
Pure Mg	13.2 ± 0.3	187 ± 4	219 ± 5	3.45 ± 0.5	57.5 ± 2
Mg/0.3 wt% GNPs	14.6 ± 0.2	197 ± 3.1	238 ± 6	3.11 ± 0.4	68.5 ± 2

Note: Rashad, M., Pan, F., Asif, M., 2015. Graphene Materials, 153–190. Mustafa, M., Abdulgadir, D.B., 2017. International Research Journal of Engineering and Technology 4 (4).

in the range of 350–400°C (Rashad *et al.*, 2015). Mg-Al alloys, such as AM60 and AZ91, are currently the most common magnesium alloys used in the automotive industry. Ceramic materials are being widely used as reinforcement material in magnesium matrix composites due to their advancement in properties such as thermal stability, lower material density, high strength, hardness and elastic modulus value (Rashad *et al.*, 2015). When compared to other ceramics, SiC particulates are popular reinforcement employed for MMC material due to its relatively high degree of wettability and stability in magnesium melt (Mustafa and Abdulgadir, 2017).

Properties of Magnesium Based MMCs (Rashad *et al.*, 2015)

- Light weight
- Excellent stiffness to weight ratio
- Low density (2/3 of aluminum)
- Excellent high-temperature mechanical properties
- Good corrosion resistance
- High specific strength
- Improved damping
- Low coefficient of thermal expansion

Tables 3 and 4 represents the comparison of mechanical properties between pure magnesium and its composite at different content and type of reinforcements.

Types of Magnesium Based MMCs

- Silicon carbide reinforced magnesium (SCRM)
- Boron carbide reinforced magnesium (BCRM)
- Fiber reinforced magnesium (FRM)
- CNT reinforced magnesium (CNT-RM)
- Aluminum oxide reinforced magnesium (AORM)
- Titanium carbide reinforced magnesium (TCRM)

Table 4 Properties of magnesium-based MMCs at different content and type of reinforcements

Materials	0.2% Yield Strength (MPa)	Specific Yield Strength (MPa)	Ultimate Tensile Strength (MPa)	Specific Ultimate Tensile Strength (MPa)	Ductility (%)
Mg	100	58	258	148	7.7
Mg-2% Cu	281	148	335	177	2.5
Mg-4% Cu	355	170	386	184	1.5
Mg-7% Cu	–	–	433	195	1.0
Mg-2% Ni	337	177	370	194	4.8
Mg-3% Ni	420	203	463	224	1.4
Mg-6% Ni	–	–	313	131	0.7
Mg-2% Ti	163	90	248	127	11.1
Mg-4% Ti	154	81	239	126	9.5
Mg-30% SiC (Particulate)	229	105	258	118	2.0

Note: Trinh, S.N., Sastry, S., 2016. Processing and properties of metal matrix composites. Mechanical Engineering and Materials Science Independent Study, 10.

Applications of Magnesium Based MMCs (Rashad *et al.*, 2015)

- Castings for gearboxes, transmissions, intermediate compressors, auxiliary gearboxes, generators, canopies, and engine components are some of the aerospace applications.
- Due to its light-weight and mechanical properties, it has potential applications in motor racing for reducing vehicle weights.

Titanium-Metal Matrix Composites (TMMCs)

Continuous silicon carbide (SiC) fibers reinforced in titanium metal matrix composite (TMMC) material is leading in aerospace applications in topmost countries, including the UK, USA, France, and China (Peng, 2005). A formidable mixture of stiffness, specific strength, resistance to creep, and fatigue at elevated temperatures is contingent by TMMCs. Advancement in the Ti-based MMC manufacturing techniques has been achieved by several solid-state processing techniques. They are foil fiber foil (FFF) method, matrix coated mono tape (MCM) method and the matrix coated fiber (MCF) method, due to the active behavior of titanium (Holley, 2013). With a very uniform and fine-grained fiber distribution in MCF, the fiber volume fraction of the maximum up to 80% can be achieved (Holley, 2013). Al-reinforced titanium-based MMCs find a wide range of applications in automotive and aerospace industries, the titanium and its alloys are rapidly becoming a part of significant research interest. These materials reveal attractive properties like high strength to weight ratio, excellent biocompatibility with chemical resistance. Such a combination of exceptional properties of these materials makes them an ideal candidate for structural, chemical, petrochemical, marine, and biomedical applications. For the past 30 years, there is a great use of TMCs in aircraft engines and airframe applications, and still being under significant development and evaluation. The main catalytic reason behind its usage for airframe applications is due to its high specific modulus. The introduction of TMCs in high-performance applications has not been straight forward due to its complexities in fabrication, and high material and implementation costs. To increase its usage for industrial applications, consistent efforts on TMCs research were made in the earlier days by the National Aeronautics and Space Administration (NASA). One such example, where six US companies came forward to join forces for the research and development for the implementation of TMCs into large gas turbine engines and form titanium matrix composite turbine engine composite consortium (TMCTECC) program (Hayat *et al.*, 2019). Titanium and Ti alloys are rapidly becoming a part of remarkable research interest for extensive applications in the automotive and aerospace sectors. These materials are light in weight and frequently shown irresistible properties, such as high specific strength, eminent chemical resistance, and exceptional biocompatibility. The combination of these properties makes them a vital candidate for structural, chemical, petrochemical, marine, and biomedical deployments (Welsch *et al.*, 1993; Leyens and Peters, 2003; Li *et al.*, 2013). The Young's modulus, resistance to wear, and heat of titanium materials are subservient to steel and nickel based alloys. TMMCs serve as an alternative to conquer these drawbacks. TMMCs have been under consequential development and evaluation in the past 30 years for deploying in aircraft engines and airframe applications (Liu *et al.*, 2006; Singerman *et al.*, 1996). The advantage of high specific modulus and high specific strength of TMMCs are the main reasons for its deployment in airframes and engine applications. TMMCs based on titanium aluminide that consist of temperature potentiality of reaching to 760°C offers a promising 50% weight reduction as compared to nickel-based super alloys for elevated temperature compressor applications (Liu *et al.*, 2006; Anderson, 1998; Salvo and Mangalaraja, 2018). The initiation of TMMCs into high-performance applications has been complicated due to the complexities in fabrication, high-cost material, and deployment costs. Due to these earlier efforts, the recent advancement and success stories of TMMCs are achievable (Welsch *et al.*, 1993).

Types of Titanium-Based MMCs

Depending on the form of reinforcements, the common TMMCs can be categorized into two groups (Welsch *et al.*, 1993):

- Continuously reinforced TMMCs
- Discontinuously reinforced TMMCs

Properties of Titanium-Based MMCs

Table 5 depicts the comparison of conventional Ti-MMC, Ti-aluminide-MMC, and super-alloys comparatively.

Applications of TMMCs

The schematic representation in the turbojet engine is shown in Fig. 11(a). US famous fighter aircraft F-22 amounts to ~39% titanium and 24% deployment of composites (Air Force Technology, 1997) and development of new generation F-35 fighter planes expecting this amount more likely to be raised. Similarly, the lower drag brace of the landing gear is achieved with SiC fiber reinforced in the TMMCs for Royal Netherlands Air Force F16 (Specialty Materials, Inc.). The actual images of the US Aircraft (F-16, F-22, and F-35) are shown in Fig. 11(b). The TMMC replacement purveys 40% weight reduction in contrast to the original one, which was produced with high-strength steel. Moreover, when compared to steel or aluminum, the metallic composite materials show efficient corrosion resistance and fatigue resistance.

Recently, for the advancement in ultra-fan engine design, the Rolls Royce approaches the testing of a carbon or titanium-based composite fan system. This system includes fan blades made of carbon or titanium with a composite casing, which reduces weight up to 1500 lb per aircraft. This composite fan system of Rolls Royce for new engine designs is shown in Fig. 12(a). This weight reduction is equivalent to the cost of an additional seven passengers. In comparison with the first generation Trent engine (TE), this engine burns 20% less fuel with lesser CO₂ emissions (Welsch *et al.*, 1993). The connecting rods and engine valves made of DRTCs are being deployed by Toyota Motors in their cars. The landing gear of a Royal Netherlands Air Force F-16 is shown in (Fig. 12(b)).

Table 5 Comparison of Ti-MMCs and super-alloys properties

Property	Conventional Ti MMC	Ti Aluminide Ti MMC	Super-alloys
Density (g/cm ³)	4.04	4.18	8.3
0° Stiffness (GPa)	200	242	207
90° Stiffness (GPa)	145	200	207
Maximum Useable Temperature (°C)	538	760	1090
0° CTE (°C ⁻¹ × 10 ⁻⁶)	7.20	7.92	13.0
90° CTE (°C ⁻¹ × 10 ⁻⁶)	8.91	9.18	13.0

Where, 0° = Direction of fiber, 90° = Transverse to direction of fiber, CTE = Coefficient of thermal expansion.

Copper-Metal Matrix Composites (CMMCs)

Distinctive properties can be achieved, such as high thermal and electrical conductivity, high strength, and excellent thermal resistance to withstand internal stresses when Al_2O_3 particles are disseminated in the copper matrix. The application includes resistance welding electrodes, lead frames, and electrical connectors (Franczak and Karwan-Baczewska, 2017). The materials for electronic packaging and thermal management deployments demand the reconcilable coefficients of thermal expansion (CTE) with those containing semiconductors or ceramic substrates, which shows effectively high thermal conduction and excellent mechanical properties. The combination of significant properties of Cu SiC-MMC materials, such as high thermal conductivity of copper (Cu) and low coefficient of thermal expansion (CTE) of SiC produced to serve as a great solution for thermal management (heat management system) (Rajkovic et al., 2010). Conventional materials such as copper/tungsten (Cu/W), copper/molybdenum (Cu/Mo), copper-Invar-copper (Cu/I/Cu), and copper-molybdenum-copper (Cu/Mo/Cu) alloys possess a low coefficient of thermal expansion (CTE) with high densities and thermal conductivities. Copper-SiC composites provide a beneficial relationship between thermo-mechanical properties with high conductivity. They consist of a lower density than copper, excellent thermal conductivity, low coefficient of thermal expansion (CTE), and better machinability (Rao, 2017). However, Cu-SiC manufacturing techniques carry the predominant challenge of preventing reaction during the densification at a higher temperature between copper and SiC, which dramatically decreases the thermal conductivity (Rao, 2017). Copper (Cu) is capaciously utilized in extravagant applications, such as integrated circuits, electric switches, and electronic packages by virtue of its distinguishable characteristics, such as high electrical conductivity, fatigue resistance, workability and corrosion resistance. However, it retains restricted mechanical properties (Franczak and Karwan-Baczewska, 2017). The copper-based MMCs are under investigation by assorted researchers (Hong, 2011; Shehata, 2009; Moghadam, 2015) for addressing the requirements for their utilization in the functional applications. The key to counterfeit materials with essential mechanical and electrical characteristics is that they should block the dislocation motions with minimizing scattering of conducting electrons to certain acceptable levels (Duarte and Ferreira, 2016). In mainstream, ex-situ or in-situ methods (Tjong, 2013) have been used as different approaches to disperse reinforcement particles in the copper matrix to improve its mechanical properties. The quantity of reinforcement appended to the metal matrix will remarkably influence the microstructure and functional characteristics of the composites (Franczak and Karwan-Baczewska, 2017). The necessary properties can be achieved by varying the amount of weight/volume fraction of the reinforcement material particles (Geim and Novoselov, 2007). The homogeneous distribution of the reinforcement particles is the most consequential factor in obtaining the composites with improved mechanical properties (Pai et al., 2004). The particle size of the reinforcements has an unassailable effect on the mechanical properties of composites. Thus, the preference must be given to the nanosized particulates as reinforcing materials (Geim and Novoselov, 2007).

Properties of Copper-Based MMCs (Ramkumar, 2018)

- Low coefficient of thermal expansion
- High stiffness (modulus of elasticity)
- Good electrical conductivity
- High thermal conductivity
- Good wear resistance

Table 6 states the quantitative values of properties of Cu based MMCs in a tabular structure.

Applications of Copper-Based MMCs

- Copper MMC composites, such as Glidcop, retains the characteristics of copper material even at higher levels of temperatures and radiation. It is deployed as radio-frequency quadrupoles (RFQs) in particle accelerators.

Table 6 Mechanical properties of copper MMC

Property	Units	Values
Density	g/cm^{-3}	2.85
Elongation at break	%	6
Tensile modulus	GPa	100
Tensile strength – longitudinal	MPa	610
Volume fraction of SiC	%	17
Yield strength	MPa	400

Fig. 13 “Green Bullet” produced with copper jacketed tungsten. Reproduced from Collins, J.M., Mikko, D., 2000. A technical report by Don Mikko, US. Association of Firearm and Tool Mark Examiners Journal. Available at: <http://www.firearmsid.com/Feature%20Articles/GreenBullets/GreenBullets.htm>.

- In electronics, because of its very high thermal conductivity, the copper-silver alloy matrix consisting of diamond particles 55% by volume known as Dymalloy is deployed for the application of multi-chip modules, which demands high-power, high-density materials.
- For high-temperature structural radiators, the Gr/Cu MMCs with high thermal conductivity are deployed.
- Cu based MMCs are used for fabricating hybrid modules, electronic relays, electricity conducting springs, and other electronic components (Ramkumar, 2018).
- The multi-node attachment for connecting trusses is made of copper-based MMCs (Rawal, 2001).
- The volcanic tuff and copper powder were mixed in a turbula rotary mixer; blends were prepared to contain 5, 15 and 30 volumetric percentages of tuff respectively and were examined. The powder metallurgy process was used for manufacturing it. This Cu based MMC is used in nozzle tips of resistance welding electrodes (Mikuła *et al.*, 2015).
- The American military researchers have developed a lead-free projectile as lethal standard 5.56 mm. It is known as “GREEN BULLET,” as shown in Fig. 13. It replaced the copper-jacketed lead core with copper jacketed tungsten tin or nylon core. This will have a positive impact on the growing environmental and health impacts of lead (Collins and Mikko, 2000).

EDM copper tungsten electrode is manufactured with powder metallurgy to take advantage of a combination of EDM properties of tungsten and copper. Excellent wear properties have been displayed by tungsten and copper integrates combining high electrical conductivity of copper and a high melting point of tungsten together.

Other Applications

The New York University (NYU) polytechnic school of engineering delineated that researchers at the school have given a practical exhibition and explanation of a freshly new MMC that as light as it can float on water (Fig. 14). Researchers have postulated that a boat/ship produced with such lightweight composites will never sink, except if some damage is caused to its structure. This newly discovered material can also assure the improvement in automotive fuel economy since it efficiently combines lightweight characteristic with the heat resistance (Anon 4, 2014; Business Communications Company, 2006).

Compared to a water density of 1.0 g/cc, a composite material containing magnesium alloy as a matrix reinforced with silicon carbide hollow particles has a density of 0.92 g/cc. It has been developed in co-operation with Deep Springs Technology (DST, Toledo, OH, US). The university also reveals that the technology used for the new composite materials can be put as prototypes for testing within three years as it is very close to maturation. Amphibious vehicles, such as the ultra heavy-lift amphibious connector

Fig. 14 MMCs that floats has potential in automobile and marine applications.

Table 7 Mechanical and tribological properties of self-lubricating metal matrix composites

Matrix	Self-lubricating phase	Mechanical Properties	Tribological properties
Al-16Si-5Ni	Graphite (5 wt%)	–	In fully lubricated condition, coefficient of friction (COF) = 0.06 against steel
Al-Al ₂ O ₃	TiB ₂	Yield stress = 52.8 ± 1.2 MPa	COF = 0.38 against stainless steel
AA6061	Graphene (15 vol%)	Young's modulus = 50 GPa	COF = 0.2 against steel
TiAl	Grpahene	–	COF = 0.35 against Si ₃ N ₄
Copper	Carbon nano tube (16 vol%)	Hardness (Rockwell P) = 19.8	COF = 0.1 against steel
Al	Graphene (1 wt%)	Hardness (Rockwell F) = 97	COF = 0.25 against steel

(UHAC), developed by the U.S. Marine Corps might particularly get benefitted from the high buoyancy to weight ratio offered by the new synthetic foams. Nikhil Gupta, a professor in the Department of Mechanical and Aerospace Engineering at NYU School of Engineering and his co-author of the study, says, “This advancement of feathery light MMCs can swing the pendulum back in approbation of metallic materials. The ability of metals to prolong elevated temperatures can be a huge headway for these composites in engine and exhaust components”. The lightweight SiC hollow spheres were produced and deployed through DST. A single sphere’s shell can successfully undergo the pressure of more than 25,000 psi before it gets ruptured, which is 100 times to the maximum pressure created in a fire hose. The hollow particles also provide impact protection to the synthetic foam because each shell acts as an energy absorber during the fracture phenomenon. The composite can be customized with respect to density and other characteristics by varying number of shells into the metal matrix according to the necessity of the application. This concept can also be deployed with other magnesium alloys that are inflammable. NYU also presumes that the new composite consists of potential applications in boat flooring, automobile parts, and buoyancy modules, along with vehicle armor. The research is being carried out in collaboration with the U.S. Army Research Laboratory.

Self-Lubricating Composites (SLC)

In sliding application, liquid or grease-based lubricants are used to facilitate relative motion between components and to minimize friction and wear. These lubricants can separate the surfaces without forming any asperity junctions (Menezes *et al.*, 2018). However, the use of liquid lubricants functionality reduces in extreme environments, such as vacuum, radiation, pressure, and temperature. At such extreme conditions, solid lubricants, such as MoS₂, hBN, graphene, and graphite, etc., are utilized. Direct application of the solid lubricants is challenging because it is difficult to maintain a uniform layer of solid lubricants between the sliding parts. To overcome this issue, SLC materials have been developed. SLC materials are hybrid composite materials where more than two types of reinforcements are incorporated in the matrix. One type of reinforcement, which is generally a hard phase (usually ceramic) enhances the physical properties of the matrix, such as strength, stiffness, etc., while the other type of soft reinforcement (solid lubricant) enhances the lubricating properties, such as reduces friction and wear. The solid lubricants have been effective in enhancing the tribological properties in metal, polymer, and ceramic matrices (Omrani *et al.*, 2017; Kasar and

Menezes, 2018; Malaki *et al.*, 2019). When the material is sliding against each other, the material gets wear against the counter surface. The solid lubricant particles embedded in the matrix will be exposed to the surface, thereby keeping the surface lubricated. A distinctive feature of self-lubricating composites is that the wear particles formed on the contact surface acts as solid lubricants, and it can reduce the friction coefficient and wear rate. Casting or powder metallurgy techniques can be used to manufacture self-lubricating metal matrix composites. A classic example of this type of SLC is the gray cast iron; it utilizes a hard iron matrix with dispersed lubricating graphite flakes. Common types of matrices used for the manufacturing of SLC are aluminum, copper, nickel, magnesium, silver, and its alloys. Implementing SLC into different mechanical systems is a solution to reduce the use of external toxic petroleum-based lubricants in a way to support the environment and to reduce energy dissipation in industrial components for strategies toward energy efficiency and sustainability. Some of the SLC materials are listed in Table 7, along with their mechanical and tribological properties:

Conclusions

The properties of the MMCs depend upon the type of reinforcements and the production processes, which influence its applications. Every year the use of MMCs is increasing, but more percentage of applications are observed in the ground transportation sectors, electronic/thermal management, and other areas. The aluminum-based MMCs have wide applications as compared to the other MMCs, which are at significant interests among the researchers. The MMCs have broad applications in the automotive sector, due to the better strength and other mechanical properties at elevated temperatures, as compared to its weight. The titanium-based MMCs have more applications in the biomedical sector due to its chemical stability with the other improved qualities. Only the aluminum-based MMCs are of booming interest amongst researchers, but the other MMCs lack the research and applications, which gives a potential topic for further investigation. There is advancement in the metal matrix nano-composites for its applications in the advanced armor system in the military department.

Introduction

The increasing demand for fuel efficiency and light weight components in automobile sectors lead to the development of advance material parts with improved performance (Natarajan *et al.*, 2006). A specific class of MMCs which has gained a lot of attention due for its potential is aluminium metal matrix composites (Al-MMCs). Al-MMCs have a big potential for several applications in automobile parts. This specific class possesses high wear resistance and high specific mechanical property, 67% lower density than cast iron and three times the thermal conductivity, thus Al-MMCs are ideal materials for the manufacture of lightweight automotive components (Prasad and Asthana, 2004). Initialisation of Al-MMCs application in automotive industry was in car engine, which utilised reinforced Al-MMCs for pistons in the Toyota diesel engine (Chawla and Chawla, 2006a; Evans *et al.*, 2003). Experimental studies have been carried out to evaluate the effect of sliding velocity and applied load on the wear characteristics of Al-MMCs (Rao and Das, 2010) which indicated some potential for application in vehicle braking system.

Automotive braking system is subjected to mechanical and thermal stresses, hence depends on a combination of properties. Thus it is hard to select a material based only on one of these properties. The material applied in brake disc must bear thermal fatigue, moreover it should absorb and dissipate quickly heat generated during braking (Cueva *et al.*, 2003). Although MMCs have been applied for brake disc, the product has not yet been highly produced and used widely for replacement of the existing iron brake disc due to high manufacturing cost for mass production (Miracle, 2005). Therefore, this indicates a potential avenue of further research in the field of MMCs and to identify its potential as a replacement for the existing conventional brake disc.

The consequences of globalisation have essentially changed the nature of world market competition (Priest and Sanchez, 2001). Subsequently, first class companies need to employ the right strategy of product development to stay ahead of the competition. They are required to implement product development (PD) strategy which can deliver product with high performance in terms of time to market, product cost and quality (Durmusoglu and Barczak, 2011). Product development plays an important role in the success of manufacturing enterprise and many researchers have enhanced their understanding to manage it strategically (Ayag and Ozdemir, 2009). Product development is concerned with parallel iterations running in a smooth operation and at the moment most influential paradigm that transpired has been the change from the “over-the-wall” strategy or sequential engineering to philosophy of concurrent engineering (McGrath, 2000). Simultaneous approach is part of concurrent engineering (CE) where it promotes parallel consideration of all design parameters where they were considered sequentially in the past. The previous method of sequential engineering has been considered inefficient, since it causes longer development time, higher cost, lower design quality and generates lower profit (Koufteros *et al.*, 2001).

According to Yang *et al.* (2006) CE stimulates simultaneous approach of design activity and other product development life cycle aspects in one working environment. Thus this would lead to product quality improvement, reduced cost, shortened design cycle, reduced time to market and fulfilled customer expectations (Xu *et al.*, 2007). Meanwhile Winner *et al.* (1988) defined CE as a simultaneous and systematic approach to the integrated design of products and their related processes, including product supports. Thus CE forms the foundation for engineers to develop product by taking into account all components of the product life cycle from conception to disposal, including quality, cost, production detail and user requirement (Hsiao, 2002).

Concurrent engineering is a philosophical strategy signifies simultaneous approach to be implemented in the product development process where a product and its manufacturing plan are developed concurrently, cross-functional activities are performed to achieve integration, and prioritize the customer's requirement in the product development process (Fatchurrohman *et al.*, 2015a,b). CE is a direct philosophy, but it has proven to be a powerful PD strategy (Kayis *et al.*, 2006). Some companies reported to have gained up to 60% reduction in time to market, up to 50% reduction in life cycle costs and a maximum 95% of reduction in engineering change demands as the results of implementing CE (Fine *et al.*, 2005).

In the area of product development the need for integration between design parameters selections has been identified by Lu and Deng (2004), where the majorities of materials selection has not been directly linked with engineering aspect coordination including manufacturing process selection, especially at the early design stage. While, Edwards (2002a,b) outlined that the research of materials in some areas is not always relevant to industrial requirements, i.e., it is not oriented to specific applications. Moreover, Ljungberg and Edwards (2003) highlighted the significance of integrated design of product and materials selection and market-oriented design. Product development is related to the selection of design parameters in the early stages as highlighted by Gironimo *et al.* (2006). Early identification of the optimal parameters is a serious job of the design process in order to satisfy

customers, while the most demanding aspect of the approach depends in the quality evaluation of optimal parameters. Whereas according to [Shai et al. \(2009\)](#), conceptual study determines the principles that govern the product and decisions made at this stage have major effect on the final product quality, cost and market share.

Product development has been an essential activity for the success of product competition especially in the fast growing and fierce competition especially in the automotive industry. The focus of product development research in the automotive industry is directed towards developing and implementing light weight – high strength materials, having main objectives to improve vehicle performance, increase fuel efficiency, reduce emissions and increase vehicle safety at competitive cost. [Fatchurrohman et al. \(2013\)](#) stated that the key of a product success in the market rely on the effectiveness of its product development. Among the advanced materials which fall under this category are metal matrix composites (MMCs) ([Prasad and Asthana, 2004](#)). Metal matrix composites (MMCs) have become an essential class of composite materials, which are intensively utilised in some of the new engineering applications. Metal functions as the primary phase (matrix) and a second phase reinforcement is embedded and distributed to achieve some property improvement. Substantial research has been aimed at the advances of these new materials with excellent strength to weight ratio. MMCs have potentials in various applications because of their very good properties in strength, stiffness, lightweight and high temperature resistance ([Basavarajappa et al., 2006](#)).

Literature Review

Metal Matrix Composites (MMCs)

The future trends in material engineering would be the development of synergy among materials for advanced applications. In line with this, the last few decades have witnessed vast growth of new materials. Conventional monolithic materials have limitations in achieving good combination of strength, stiffness, toughness and density. To overcome these shortcomings and to meet the ever increasing demand of modern day technology, composites are most promising materials of recent interest. It is widely known that metal matrix composites (MMCs) fall under the category of composites materials. These materials are increasingly being used in the automobile, aircraft, and space industries ([Miracle, 2005](#); [Chawla and Chawla, 2006b](#)).

A business assessment by [Swift \(2009\)](#) accounted that the world market for MMCs is growing and used up to 4.1 million kg of materials in 2007 and 4.4 million kg in 2008. Furthermore, it is predicted to increase to 5.9 million kg in 2013, for a compound annual growth rate (CAGR) of 5.9%. The ground transportation sector has the biggest share of the market and used 2.4 million kg in 2008; this should reach 3.2 million kg in 2013, for a CAGR of 5.5%. Electronics or thermal management applications have the second largest share and it used 1.4 million kg of MMCs in 2007, this increased to 1.5 million kg in 2008 and is expected to grow at a CAGR of 6.5% to reach 2.1 million kg in 2013.

MMCs can be defined as materials system attained from the result of physical combination of component materials which remain distinct throughout the fabrication history ([Clyne and Withers, 1995](#)). Unlike conventional alloys, including eutectics or alloys containing precipitates or segregated inclusions, in which various phases present are all formed from homogenous melt during solidification and/or heat treatment. MMCs also conduct heat and electricity, which is important attribute in some applications. In some cases, MMCs can be welded or easily fastened to other metallic components ([Evans et al., 2003](#)). MMCs also offer outstanding properties such as high strength to weight ratio, high torsional stiffness, good corrosion resistance and good tolerance characteristics and versatility to the designer ([Miracle, 2005](#)).

While [Kalpakjian and Schmid \(2010\)](#) compares MMCs with conventional polymer matrix composites, with MMCs having higher elastic modulus, resistance to elevated temperatures, radiation and moisture, higher toughness and ductility, better electrical and thermal conductivity. On the other hand the reinforced material may be difficult to fabricate, and the available experience in use is limited. Other limitation is difficulties in processing parts. Polymer and metal matrix composites thus have rather different characteristics, and thus they also have different fields of application

Matrix Materials

In MMCs system the matrix material acts as the primary phase, having a continuous character. Matrix is usually more ductile and less hard phase. It holds the dispersed phase in its embedded place. The matrix also acts as the medium to transfer load to reinforcement, protect reinforcement from adverse conditions, and prevents brittle crack propagation ([Groover, 2007](#)). Numerous metals have been used as matrices. Beside aluminium some of the most important metals for matrices are titanium, magnesium, and copper alloys.

Significance of aluminium alloy as matrix material

In this product development study the focus of research is on the selection of aluminium metal matrix composites (Al-MMCs), therefore the reason over its selection will be discussed in this section. Aluminium alloy as matrix material is used because of their low density and excellent strength, toughness and corrosion resistance, it has been used widely in the automotive and aerospace fields ([Torrallba et al., 2003](#)).

Al-alloys provide a good matrix for the development of particulate composites which are less expensive and exhibit high mechanical properties. Reinforcing an aluminium alloy with reinforcement material produces a material that displays physical and

mechanical properties of both the metal matrix and the reinforcement material (Evans *et al.*, 2003). For instance, the toughness and formability of aluminium can be combined with the strength of reinforcement material. On a weight adjusted basis, many aluminium based composite materials can outperform cast iron, steel and many alloys in a wide variety of applications (Seah *et al.*, 2003).

The outstanding strength to weight ratio of Al-MMCs have benefits in the transportation segment such as lower fuel consumption, less noise and lower airborne emissions. Other advantages of Al-MMCs compared to unreinforced materials are greater strength, improved stiffness and reduced weight (Surappa, 2003). Furthermore, Al-MMCs have very good properties for high temperature applications with controlled thermal expansion coefficient, enhanced and tailored electrical performance, improved abrasion, wear resistance and improved damping capabilities (Prasad and Asthana, 2004).

Reinforcement materials

The reinforcement material has stronger properties than the matrix material and reinforcement material must be available in sufficient quantity and at an economical rate. Recent researches are directed towards a wider variety of reinforcements for the range of matrix materials being considered, since different reinforcement types and shapes have specific advantages in different matrices.

MMCs are classified based on the type of reinforcement material used which can be divided into three major categories: Particulate, whiskers or discontinuous fibre, and continuous fibre. The most widely used for reinforcement material is silicon carbide (SiC).

Significance of particulate reinforcement

Particle reinforced composites are inexpensive compared to continuous fibre reinforced composites. Cost is an important and essential parameter, particularly in applications where large volumes are required (e.g., automotive applications). The important properties of particulate reinforcement include suitability for high temperature applications, enhanced modulus, increased thermal stability, better wear resistance and relatively isotropic properties compared to fibre reinforced composites (Chawla and Chawla, 2006a).

Manufacturing process of MMCs

Modern metallurgy uses various methods for fabricating MMCs including various types of casting, processes of powder metallurgy, plastic working, spraying, deposition and many others. The choice of a particular fabrication method is mainly determined by the following factors (Tchubarov *et al.*, 1995):

- (1) Type of source materials of matrix and reinforcing agent;
- (2) The possibility of introducing the reinforcing agent into the matrix without damaging;
- (3) Forming a secure bond at the reinforcing agent-matrix interface;
- (4) Maximum realisation in the material properties of its component;
- (5) Attaining the desired reinforcing agent distribution pattern inside the matrix;
- (6) Combining material fabrication with part manufacture;
- (7) Economic efficiency of the process.

A very important consideration in choosing the method is the availability of the desired equipment and the type of end-product. The selection of suitable process engineering is based on the desired type of quantity and distribution of reinforcement, the matrix alloy and the application. By altering the manufacturing method, the processing and the finishing, as well as by the form of the reinforcement components it is possible to obtain different material properties, although the same composition and amounts of the components are involved. Metal matrix composites can be made by liquid, solid, or gaseous state processes (Surappa, 2003).

In this research the selection of manufacturing process is based on production of MMCs by liquid process. In this process, the particulates are integrated into a molten metallic matrix by means of various techniques.

Conceptual research in MMCs

This section explores conceptual work related to MMCs, although this area of study is still in its early phase. It indicated that conceptual and simulation works are potential avenues to contribute for better understanding of MMCs. There are few research works which have been published in the literature; the following paragraphs review the current studies.

Schoutens and Zarate (1986) had presented conceptual design modelling based upon the representations of structural indices for the selection of MMCs materials as substitutes for conventional materials. Technical criteria and operational and cost criteria are used for design considerations. The relevant material property equations are used to derive structural indices. The performance of metal-matrix composites and conventional material are compared in terms of weight-to-strength ratio, impact resistance, efficiency of columns and plates, flexural rigidity, structural efficiency indices for plates and shells, and the work of fracture.

Fatchurrohman *et al.* (2015a,b) had analysed an approach in lightweight and high strength in automotive components with the used of matrix composites. In particular, they had stated that the aluminium based metal matrix composites (Al-MMCs) have some good expectation as a material for several applications in automotive industry. On the other pressing matters, they had also

determined if the material selection could make an impact to the environment, in terms of recyclability, less energy consumption, minimal or none pollution and others environment related.

Talreja (1995) performed conceptual framework for interpretation of fatigue in MMCs. Fatigue data for different MMCs systems are evaluated with the interpretative framework and some observed trends are clarified. Approaches to fatigue modelling are explained for the different regions of performance interpreted by the fatigue diagram. However, further improvements are necessary for completion of database system including manufacturing information and addition of other material property such as yield strength prediction module.

A conceptual study had been performed by Legzdins *et al.* (1997), through the development of an expert system to support engineers in the selection and design of MMCs. The model consists of a dynamic hypertext interface integrated into an expert system exploring mechanical and thermo-physical property data for matrix alloys and reinforcement materials, MMCs data are stored in databases accessed by the expert system. The system includes information on suitable manufacturing techniques. A case study demonstrating the use of the system for selecting MMCs for cryogenic applications is presented.

Modelling with database sources also performed by Zhang *et al.* (2008a,b), MMCs are classified into heterogeneous composite materials and they included functionally gradient materials with a periodic microstructure, respectively. With the database prototype and the methods developed, designers can not only select the suitable materials from the material database to satisfy their critical design requirements, but also can design and add their own special material property into the database. However, due to the variety of materials, further development, refinement and improvement are needed for the material database.

Zhang *et al.* (2008a,b) have progressed into components design to select suitable or optimal materials for heterogeneous material comprising MMCs in the scope of regions during the design of such a component. Their material compatibility or similarity has to be considered, for which an effective evaluation method of the material similarity is needed. In this work, the definitions, evaluation criteria, and calculation formula deductions of material affinities including physical and chemical affinities are developed and described in detail.

Another component design study was performed based on Axiomatic Design and developed by Chen and Feng (2003). They investigated heterogeneous materials including in this class MMCs materials properties. The procedure started with designing component's configuration according to the performance requirement, then determining material properties in different portions of the component followed by selecting optimal material constituent to satisfy material property requirements and various constraints. Finally optimizing the factors of configuration was based on the material selection. The techniques developed have progressed towards design, where it is a significant progress towards articulation of material properties and manufacturing parameters into product development strategy.

Development on Automotive Brake Disc

Brake disc is a vital part in an automobile from passenger safety point of view. It has a significant role in a vehicle performance due to its concern to reduce or stop a vehicle's motion in a normal or critical condition. Fatchurrohman *et al.* (2013) stated that intensive research had been made to produce lightweight and high performance components, which ultimately lead to fuel efficiency and sustainability. The material properties of the brake disc have a significant task by influencing the thermal conductivity and heat dissipation during vehicle braking (Adebisi *et al.*, 2011). Moreover, the material used for brake disc should possess stable and reliable wear properties with high durability (Maleque *et al.*, 2010).

Gray iron has good thermal conductivity due to the graphite phase, which is an excellent thermal conductor. Cueva *et al.* (2003) investigated the wear resistance of three different types of gray cast iron (GCI) used in brake discs. It was studied and compared with the results obtained with a compact graphite iron (CGI). However, when compact graphite iron was tested with lower applied pressures and same friction forces sustained by the gray iron rotors, CGI presented the same performance, as did the gray cast iron. The major constraint of using CGI or cast iron is the weight factor. The weight of brake components has a significant influence on the handling, driving and steering behaviour of a vehicle. It is therefore of interest to investigate lighter weight alternatives to CGI or cast iron brake discs (Kainer, 2006).

The potential of Al-MMCs as brake disc material

In terms of weight, MMCs brake disc designs have a potential to a 60% reduction when compared to cast iron. In addition, aluminium metal matrix composites (Al-MMCs) rotors have the potential to outperform their gray iron counterparts in terms of their mechanical properties and practical application (Bruski, 2000). According to Fatchurrohman *et al.* (2016), Al-MMCs had gained a lot of attention due to its potential as an advanced material part. Studies performed by Natarajan *et al.* (2006) investigates the wear behaviour of Al-MMCs sliding against automobile friction material has been compared with the conventional gray cast iron. A gradual reduction of friction coefficient with increase of applied load is observed for both cast iron and Al-MMCs materials.

Yang (2003) studied MMCs brake disc using pin-on-disc apparatus against heat-treated steel counter surface, giving emphasis on the parameters such as wear coefficient as a function of applied pressure for alloy and composite for various sliding velocities. Wear coefficient of the alloy was noted to be significantly higher than that of the composite and is suppressed further due to addition of silicon carbide particles and applied pressure.

Sahin (2003) studied the wear rate of the composite and the matrix alloy which has been expressed in terms of the applied load, sliding distance and particle size using a linear factorial design approach. It was demonstrated that the composite exhibited a low wear rate compared to the unreinforced matrix material for both cases.

Uyyuru *et al.* (2006) investigated tribological performance of Al-MMCs against brake pad under dry sliding conditions. It was observed that a heterogeneous layer was formed over the worn surfaces during the wear tests. The presence of “tribo” layer was indicated to cause two phenomena; which are acting as a lubricant layer and source of wear debris. The effect of speed, on the wear rate seems to be less dominant compared to load.

Gultekin *et al.* (2010) had performed a research of sintered copper alloy reinforced with graphite particulates brake pads against cast Al-MMCs brake disc and the effects of applied load on the coefficient of friction have been reported. The experimental results proved that the brake disc and the pad have high wear resistance.

Product Development

Product Development (PD) is crucial in the development and improvement of a new product. Fatchurrohman *et al.* (2012) shows that the process involves a very conceptual selection, in which it is an activity that engage with numerous types of data, including technical customer specifications and current design developments. Marini *et al.* (2016) stated that the general conceptual design are comprises of material selection, design concept and material selection. PD is used to interpret the customer's need and requirement into a product. The initial stage of PD is the most important as it involve the time, cost and others matter related to the production. Poor decision might lead to a huge cost and product failure. The development process can be tasking but ultimately lead to good result that can save time, cost, quality and also improve the performance of the product.

Many tools are developed with each of they own function in evaluating a design concept, which compromise of different effective factors such as the customer's requirement, current market competition and designer intentions and functionability. Some of the tools involve are Quality Function Deployment (QFD), which it used to ensure the customer's voice are engaged throughout the product design and development process, as well as improving the quality. It comprises a matrix of conceptual map that linking the interfunctional planning and communication. The QFD system is categorized into phases of product, process and production planning, as well part deployment. This tool is mainly used in making complex decision in product planning.

Multi Criteria Decision Making (MCDM) consists to Analytic Hierarchy Process (AHP) and Analytic Network process (ANP). AHP is used in expressing the general decision operations by the decomposing a problem into a multilevel hierarchy structure comprises of objective, criteria and alternative. It is effective in breaking down multi-criteria problem in hierarchy way to make decision making. ANP however, is more generalized from AHP, in which it allow interrelationships complex among decisions in levels and attributes. It also requires the opinion of the designer in order to carry out pair-wise comparisons.

Research Methodology

Introduction

The research framework was constructed based on simultaneous approach where parallel activities were stimulated and encompasses the entire product life cycle. Simultaneous approach was applied effectively involving the product and process data management coupled with engineering knowledge. Moreover by implementing simultaneous approach, product design and manufacturing entities are developed to bring new product quickly and reduce defects by iterative and substantive considerations in the early phase of product development process (Hsiao, 2002). By means of early consideration of product information, different phases of the problem could be overcome while at the same time the design parameters are evolving. The proposed framework is referred as Integrated Conceptual Selection (ICS) framework. The proposed ICS framework is portrayed in Fig. 1.

Product investigation

This is the first phase in the product development and it is pivotal in determining the success of a product. Product investigation or commonly known as market investigation is an activity of taking information of current and future trends of customers and external factors such as competition into consideration when making decisions. The use of market information has a positive consequence on the product development (Sethi *et al.*, 2001). Whereas, Cooper (2003) informed that there are products which failed due to incorrect product investigation and market analysis thus unable to meet the customer expectations. Product investigation covers the activity of collecting information from three prominent sources, this include product investigation among users (PI-USER), product investigation from the industry (PI-IND) and product investigation from scientific sources (PI-SCI).

Information was collected from users through review of customer opinions on the product. While industrial information was collected via technical reports and patents from industrial sector. Finally, scientific information was surveyed from research papers and articles from the scientific community. The product investigation regarding brake disc involved a thorough research from various sources including reports. The compilation below summarises the findings from this activity.

- (1) “I wish only I had painted the centre hubs...they have rusted after 5000 miles” (Tire track, 2012).
- (2) “Previous MMCs brake rotors were prone to “cook” or even crack under track use” (Forum Lotus, 2012)

Fig. 1 Integrated Conceptual Selection framework.

- (3) "The weight reduction is unsprung weight...has the potential to improve handling and ride quality as well as improve fuel economy and hard braking performance" (Design News, 2012).
- (4) The most appropriate material for a brake rotor is ideally having rubbing surfaces which operates at a significantly reduced temperature range (Topouzian and Riley, 1996).
- (5) Increased stiffness. Management of thermal expansion. Improved wear resistance. Improved high temperature. High performance vibration damping. Weight reduction (GE Engineering Materials, 2012).
- (6) Stable frictional behaviour over wide range of temperatures. High heat removal. Dimensional stability to reduce vibrations effect. High corrosion resistance to de-icing compounds. High durability. High wear resistance. Lightweight. Overall cost competitiveness (Wall et al., 2006).
- (7) Low pollution rates and low in energy consumption during manufacture, assembly, usage and reprocessing. The material for brake disc must be recyclable (Bakkelund and Storen, 2010).
- (8) Able to sustain torque loads from braking. Stable frictional behaviour at service temperatures. High heat absorption. High thermal conductivity. Excellent machine-ability. Inexpensive raw material. Low processing costs (Ihm, 2013).
- (9) The weight of brake mechanism, has a major influence on the handling, driving and steering behaviour of an automobile. It is therefore of interest to investigate lighter weight alternatives to gray cast iron brake rotors (Buschmann, 2006).
- (10) The tendency of brake rotors is to achieve light weight, high mechanical properties and steady-state friction level (Zhang and Feng, 2011).
- (11) Reinforcements of hard ceramic particles, in ductile metallic matrices can produce composites with considerably higher stiffness and yield strength compared with the unreinforced matrix alloys (Mazahery and Shabani, 2012).
- (12) For the success of MMCs application, cost is the key factor for wider application in modern industry, although potential benefits in weight saving, increased component life, and improved recyclability should be taken into account (Hashim et al., 2001).
- (13) The wear property of MMCs was found to be low, because of the presence of the hard particles present in the MMCs which acts as the load bearing member and abrasive nature (Gultekin et al., 2010).

The information collected from the product investigation was translated and mapped into product performance indicators. It has been identified five significant product performance indicators as illustrated in Fig. 2. The complete mapping is presented in the Appendices. Moreover, these indicators acted as a basis to develop the product specification which is elaborated further in the next section.

Product specification

The mapping between product performance indicators into product specifications showed a direct correlation could be drawn and thus the product specification was identified after the evaluation of product investigation. It was considered as a technical document organised early in the product development which acts as a requirement standards necessary for product design. According to Pugh (1991) product design specifications could be classified into several items, such as, performance, environment, maintenance, and service

Fig. 2 Product performance indicators.

Fig. 3 Product conceptual parameters.

life. However, in this framework the product design specifications were merged and classified into two major design parameters which have the most influence on the outcome of conceptual design. By identifying the product specifications, it enables a concurrent and comprehensive consideration of all design aspects. In this study the product specification was translated into nine sub-parameters under concept parameters of manufacturing process and material as shown in Fig. 3.

Concurrent network

This section discusses in detail the concurrent network (CN) as part of the new MCDM technique. The CN phase combines concurrent or simultaneous approach and ANP procedure. The strategy was applied in a generic framework for synchronised considerations of information from product investigation and product specification to obtain the product performance. Furthermore, concurrent approach (CA) was used for decomposition of product performance into conceptual aspects which were the manufacturing process and material parameters. The parameters were linked into a network, where product performance and design parameters were analysed and identified each performance's influence to the concept parameters. Then the sub-concept parameters were analysed for their interdependence relationships. This was the reason why ANP was used to perform interaction

Fig. 4 The work flow of concurrent network.

Fig. 5 The work flow of analytical network process.

and interdependence ratings among various parameters in conceptual design clusters. Moreover, pair-wise comparisons were performed to compare concept parameters and sub-concept parameters. The final result from CN analysis was the global and local weights for each sub concept parameters. For further clarification, [Fig. 4](#) depicts the work flow of CN method.

Analytical network process

Analytical network process (ANP) method involves a number of logarithm steps ([Lee et al., 2009a,b](#)). [Fig. 5](#) explains how these steps were taken to analyse interactions between the product parameters. In this study, Super Decision™ and Microsoft Excel™ commercial softwares were used to perform the ANP calculations.

(1) Network model construction

- (a) The conceptual design problem was decomposed into a network where nodes correspond to concept parameter clusters. Connections between clusters were established and loop arrows symbolised relationships between elements inside a cluster ([Fig. 6](#)).

Fig. 6 Cluster network structure.

- (b) Identify elements of sub concept parameter in a cluster which may influence some or all the elements of any other cluster. The relationships among sub concept parameters in the same concept parameter cluster also could exist and connected.
- (2) Pair-wise comparisons and priority vectors
 - (a) Elements of sub concept parameter in each concept parameter cluster were compared pair-wisely with respect to their impacts on an element in same the cluster.
 - (b) In addition, pair-wise comparisons were made for interdependency among elements outside clusters. Cluster weights were required to weight the super-matrix at the next phase, clusters were also compared pair-wisely with respect to their impacts on each cluster.
- (3) Super-matrix formation and transformation
 - (a) The local priorities were entered into the appropriate columns of a super-matrix, which was a partitioned matrix where each segment represents a relationship between two elements within a cluster and two elements in different clusters.
 - (b) The super-matrix of a system of N clusters is described as the following: C_k is the k th cluster ($k = 1, 2, \dots, N$) which has n_k elements denoted as $ek_1, ek_2, \dots, ek_{n_k}$. As inferred in Eq. (1), a matrix segment, W_{ij} , represents a relationship between the i th cluster and the j th cluster. Each column of W_{ij} is a local priority vector obtained from the corresponding pairwise comparison, representing the importance of the elements in the i th cluster on an element in the j th cluster (Saaty, 2004a, b).

$$\begin{array}{ccccccc}
 & C_1 & \cdots & C_k & \cdots & C_N & \\
 & e_{11} \cdots e_{1n_1} & \cdots & e_{k1} \cdots e_{kn_k} & \cdots & e_{N1} \cdots e_{Nn_N} & \\
 C_1 & e_{11} & & & & & \\
 & \vdots & & & & & \\
 & e_{1n_1} & & & & & \\
 & \vdots & & & & & \\
 & e_{k1} & & & & & \\
 w = C_k & \vdots & \left(\begin{array}{cccc} w_{11} & \cdots & w_{1k} & \cdots & w_{1N} \\ \vdots & & \vdots & & \ddots & \vdots \\ w_{k1} & \cdots & w_{kk} & \cdots & w_{kN} \\ \vdots & & \vdots & & \ddots & \vdots \\ w_{N1} & \cdots & w_{Nk} & \cdots & w_{NN} \end{array} \right) & & \\
 & e_{kn_k} & & & & & \\
 & \vdots & & & & & \\
 & e_{N1} & & & & & \\
 C_N & \vdots & & & & & \\
 & e_{Nn_N} & & & & &
 \end{array} \quad (1)$$

- (c) Then, the supermatrix was transformed into the weighted supermatrix each of whose columns sums to one. This 'column stochastic' feature of the weighted supermatrix allows convergence to occur in the limit supermatrix.
- (d) A recommended approach to obtaining the weighted supermatrix was to determine a cluster priority vector for each cluster, which indicates relative importance of influences of other clusters on each cluster. This could be done by conducting pairwise comparisons among clusters with respect to the column cluster.
- (e) The resulting priority vector was then used to weight the matrix segments that fall in the column under the given cluster. The first entry of the vector was multiplied by all the elements in the first matrix segment of that column, the second

entry by all the elements in the second segment of the column and so on. Repeating this weighting procedure for all the column clusters produces the weighted supermatrix.

- (4) Final priorities
 - (a) When the super-matrix covers the whole network, the final priorities of elements were found in the corresponding columns in the limit centrality by raising the all the variables in the weighted super-matrix to powers by multiplying it times by itself.
 - (b) The reason for this was to capture the transmission of influence along all possible paths of the super-matrix. The entries of the weighted super-matrix represent the direct influence of any element on any other element, but an element can influence a second element indirectly through its influence on a third element that has the direct influence on the second element.
 - (c) Such one-step indirect influences were captured by squaring the weighted super-matrix, and two-step indirect influences were obtained from the cubic power of the matrix, and so on.
 - (d) Raising the weighted super-matrix to the power $2k + 1$, where k is an arbitrarily large number, allow convergence of the matrix, which means the row values converge to the same value for each column of the matrix. The resulting matrix is called the limit centrality matrix, in this study it is represented by the limit centrality table.

Results and Discussion

Concurrent Network

The first part of the conceptual design is the concept selection by using concurrent network (CN) which combines CE strategy and ANP method. In this phase CE strategy was implemented by simultaneous consideration and decomposition of product performance into conceptual parameters which include the manufacturing process and material concept parameters. In this research problem ANP method allowed interaction and feedback between the conceptual parameters thus solving complex situations and represents comparisons in the analysis. The outcomes from CN technique were cluster weights, unweighted supermatrix, weighted supermatrix and limit centrality table (Fig. 7). The cluster matrix contains the weights of the main clusters, whereas, the unweighted supermatrix contains the local priorities derived from the pair-wise comparisons throughout the network.

Then it is followed by the result from the weighted supermatrix which was obtained by multiplying all the variables in concept sub-parameters by the corresponding weight of importance for each concept sub-parameters. The final result in the CN phase is the limit centrality table which was attained by raising the weighted supermatrix to powers by multiplying it times by itself; this table contains the local and global weights of the sub concept parameters.

The first discussion will look into cluster in the CN network which is equivalent to a class, and subclasses correspond to elements of conceptual parameters. In the context of CN, the network model comprised of Product, Performance and Concept Clusters. Thus, the importance of clusters was evaluated with respect to impacts or influences on other cluster. The cluster network was constructed based on the relationships represented in Fig. 8.

Product cluster was solely translated and influenced by the performance cluster. Whereas, comparisons were made between concept clusters, in this investigation the concept clusters were compared with respect to the performance cluster. The result indicates that the two main concept clusters (i.e., manufacturing process and material clusters) have the same weight, i.e., 0.5. This means that the concept parameter clusters have the same influence on the performance cluster.

Analysis of parameters within the cluster was related by an outer dependence where parameters in a cluster can depend on some parameters at another cluster. Outer dependencies are represented by two way connector arrows, therefore parameters in cluster can influence the parameters in the other cluster and vice versa (Milani *et al.*, 2012). Inner dependence refers to the condition when parameters of a cluster influence each other (Percin, 2008). In the network (Fig. 9), the outer dependencies are

Fig. 7 Concurrent network results.

Fig. 8 Cluster network with cluster weights.

Fig. 9 Cluster network with conceptual parameters.

represented by two-way arrows and inner dependencies by looped arcs. **Fig. 10** shows the analysis as perform in Super Decision™ software.

Unweighted supermatrix

A supermatrix is a two-dimensional matrix of elements by elements under manufacturing process and material concept clusters. The supermatrix was produced from the pairwise comparison matrices of interdependencies and it allows a degree of the effects of interdependence that exists between the elements in the network (Meade and Presley, 2002).

The unweighted supermatrix (USM) (Table 1) contained the result from the pair-wise comparison of all elements for each individual cluster throughout the network, hence the number of comparisons was defined by the number (non-zero) values in the USM and calculated using Eq. (1). The first column A reflects the priorities of the product performance parameters with regards to the goal. The thermal performance (THP) had the highest priority with a score of 0.2123, and then followed by mechanical performance (MEP), thermal performance (THP), structural performance (STP), environmental performance (ENP) having the same priority of 0.1996 and finally cost competitiveness (COC) with a score of 0.1889.

In the following section of the USM refers to the manufacturing process cluster the local priorities. For instance, the sub-concept parameters of primary process (PRP), secondary process (SEP), manufacturing cost (MNC) and environment impact (ENI) with respect to mechanical performance (MEP) were 0.5666, 0.2845, 0.1071, 0.0418. This indicates that primary process (PRP) was

Fig. 10 ANP as performed in Super Decision™.

more significant to other sub-concept parameters in regards to the mechanical performance (MEP) and then the next priorities were followed by secondary process (SEP), manufacturing cost (MNC) and environment impact (ENI). The priorities of other relationships between manufacturing process parameters and performance parameters can be referred from columns B to F and rows 7–10.

While the inner-dependence within the manufacturing process cluster, for instance in the case of manufacturing cost (MNC) at column I the inner-dependence comparisons of sub-concept parameters refers to primary process (PRP), secondary process (SEP) and environment impact (ENI) with respect to manufacturing cost (MNC) and the results were 0.6175, 0.2968, 0.08563. This means that primary process (PRP) had higher effect and more significant compared to secondary process (SEP) by 2.08 times and to environment impact (ENI) by 7.21 times. While secondary process (SEP) was 3.47 more significant compared to environment impact (ENI) in respect to manufacturing cost (MNC). Whereas, the other significance weights of the interrelationships of sub-concept parameters within the manufacturing process cluster can be referred from column G to column O and row 7 to row 10.

The relationship between material parameters and performance parameters show for instance the local weights of the sub-concept parameters of mechanical property (MEC), thermal property (THE), physical property (PHP), material cost (MAC), environment compatibility (ENC) with respect to thermal performance (THP) were 0.0497, 0.6386, 0.2006, 0.0716, 0.0399. This refers that the mechanical property (MEC) having the highest importance and the most influence to the thermal performance (THP), and followed by sub-concept parameters of thermal property (THE), physical property (PHP), material cost (MAC), environment compatibility (ENC). The complete set of weights referring to other relationships material parameters and performance parameters can be inferred at column B to column F and row 11 to row 15.

Inside the material cluster, the interrelationships between sub-concept parameters were analysed. For example, under the column L – thermal property (THP), the values represent the importance of mechanical property (MEC), physical property (PHP), material cost (MAC), environment compatibility (ENC) with respect to thermal property (THE). The results in sequence were 0.4045 (MEP), 0.4336 (PHP), 0.1299 (MAC) and 0.0319 (ENC); this indicates that the physical property (PHP) had the highest influence to the thermal property (THE) by 1.072, 3.338, 13.59 when compared to mechanical property (MEC), physical property (PHP), material cost (MAC), environment compatibility (ENC) respectively. The next significance of influence to thermal property (THE) in orderly manner was mechanical property (MEC), material cost (MAC) and environment compatibility (ENC). The rest of interdependence relationships within the material cluster are shown in column G to column O and row 11 to row 15.

Weighted supermatrix

The next phase involve the transformation of the USM into the weighted supermatrix (WSM) as in [Table 2](#). It was performed by multiplying each elements of the USM by the corresponding cluster weight.

This was performed in order to obtain the normalised scores for all the elements and hence able to compare each element to another in terms of its priority. The normalised matrix is achieved when the elements have non-zero numbers and the columns add up to one (i.e., column stochastic), it is then referred as the WSM ([Saaty, 2004a,b](#)).

The first column in the WSM was the same as in the USM, it presents the priorities of the performance parameters in regards to the goal cluster. The priorities which referred to the relationship between concept parameters and performance parameters were presented in normalised weight. For instance in column D, which refers to structural performance (STP) the rank of manufacturing process was mostly influenced by primary process (PRP) – 0.2655, followed by secondary process (SEP) – 0.1493, manufacturing cost (MNC) – 0.0633 and environment impact (ENI) – 0.0204. This indicates that the achievement of in the structural performance was influenced mostly by primary process (PRP) quality and the second most influential was the secondary process (SEP). Whereas, in the material conceptual cluster, the most significance influencing the structural performance parameter was mechanical property (MEC) with a score of 0.2783 and followed by thermal property (THE) – 0.5729, physical property (PHP) – 0.1214, material cost (MAC) – 0.02991 and least influential was environment compatibility (ENC) – 0.01302. This interpretation could also be applied to column B to F, row 7–15.

Whereas, the inter-dependence values between the within the manufacturing process parameters and within the material cluster were also normalised. Hence, for example under column secondary process (SEP) the sub-concept parameter which had the strongest relation was primary process (PRP) with priority of 0.3246 followed by manufacturing cost (MNC) – 0.1395 and finally environment impact (ENI) – 0.03597. In the material cluster, the results could also be analysed, for instance the relation under column O – environment compatibility (ENC), this was an interesting results since all the sub-concept parameters i.e., mechanical property (MEC), thermal property (THE), physical property (PHP) and material cost (MAC) have the same importance related to environment compatibility (ENC) with score – 0.125. This indicates that the other sub-concept parameters under the material cluster have the same degree influence to the environment compatibility (ENC). This understanding is applicable to column G to O, row 7–15.

Limit centrality

As the WSM covers the network connections between clusters of product, performance indicator, concept parameters, the final priorities of the manufacturing process parameters and material parameters were ranked and scored for its level of importance. This was done by using the limit centrality table (LCT). The LCT was derived by raising all the values in the WSM to powers by multiplying it times by power $2k + 1$, where k is an arbitrarily large number until it stabilises. Thus, when the columns of values were the same for every column, the LCT had been attained and the matrix multiplication process was stopped ([Saaty and Vargas, 2006](#)). In this case study, the limit centrality represents the overall significance of sub-concept parameters in terms of impacts and

influences on each other and with regards to the performance parameters, taking into account the direct and indirect influences into consideration. The LCT of nine sub-concept parameters is specified in Table 3. From this process, the global weights were obtained. Next the global weights were normalised by cluster weights to obtain the local weights for each element of sub concept parameters in the network. The value of the local elements was the most important for the next step of the MCDM procedure.

In the manufacturing process cluster the primary process (PRP) parameter has the highest score, which means that this sub-concept parameters was the most important to be considered to achieve the required performance of the product. The ranking was followed by manufacturing cost (MNC), secondary process (SEP) and the last was environment impact (ENI). In the material cluster, the ranking was dominated by mechanical property (MEC), which not an expected result since previously the thermal performance (THP) had the highest weight. This could be explained by other performance parameters which their achievability

were relied more on the mechanical property (MEC) than the other sub-concept parameters. The ranking of other sub-concept parameters was physical property (PHP) followed by thermal property (THE), material cost (MAC) and environment compatibility (ENC).

Conclusions

The research described in this study has been concerned with the material selection and performance using Al-MMCs for brake disc. It was defined with five indicators of product performance, which was then decomposed and analysed into the sub-conceptual parameters of the manufacturing process and material.

The investigation of the dependency and relationship between these parameters were carried out using the ANP method. The results were indicated in the matrices and in the limit centrality table. The cluster matrix indicated the weights for each cluster. The unweighted supermatrix contained the local priorities, while the weighted supermatrix indicated the normalised priorities. Finally, the limit centrality table contained the local and global weights of the sub-conceptual parameters. Also, the product development of MMCs brake disc was performed by means of the Integrated Conceptual Selection (ICS) framework.

Although the results presented in this study have demonstrated the effectiveness of the proposed approach, as well as the new MCDM technique, the local weights of the sub-conceptual parameters will be implemented in the next stage of the analysis, which is to analyse and obtain the ratings of the technical specifications.

Glossary

Electronic packaging density Number of components per unit volume in an electronic device.

Fretting Wear Type of wear characterized by low amplitude oscillatory motion in the range of few microns.

Heat Sink A device or substance which absorbs unwanted or excessive heat.

Hybrid Composites Composite materials with more than one reinforcement.

Magnetization Measure of density of magnetism.

Monolithic material Material which is composed of only one material.

Specific Stiffness Ratio of elastic modulus to weight.

Specific Strength Ratio of ultimate tensile strength to weight.

Introduction

Materials have been connected and coexisted with humankind for fulfilling diverse needs. Composites are a class of materials, which are made of two or more different monolithic materials to produce a unique blend of properties. There are many composite materials in nature. Wood, bones, silky threads and shell of invertebrates are few examples of composites existing in nature (Ali *et al.*, 2017). There are several classifications of composite materials depending on the criteria used to classify these materials. Most general type of classification is based on the type of matrix materials used in these composites. Based on the type of matrix material used, composites are classified into four types: metal matrix composites, ceramic matrix composites, polymer matrix composites and intermetallic matrix composites. Each type of composite may be divided further into many subtypes depending upon the type of reinforcements used. Composite materials are intrinsically heterogeneous and immiscible when mixed. The matrix and reinforcement remains mechanically separate phases but adequately bonded to each other without forming a solid solution.

Metal matrix composites (MMCs) can be designed and synthesized by reinforcing particulates (particles), fibers or whiskers in an alloy or a metal. These metal matrix composites generally have superior properties and perform better than monolithic alloy or metal in its stated application. The most exciting feature of these metal matrix composites in contrast to monolithic metal/alloy are its versatility in design. They can be tailor made to specific properties by controlling the matrix and reinforcement phases depending upon the requirement of specific application. This feature offers enormous possibilities of designing new metal matrix composites for highly challenging and niche applications. Density, specific stiffness, thermal conductivity, high temperature strength, damping capacity, energy absorption capability and tribological behavior are some of the properties, which can be manipulated, and tailor designed in metal matrix composites.

Metal matrix composites have been highly used in structural applications where low weight combined with high strength and high stiffness is required. They are referred as high specific strength and high specific stiffness of materials. Most notable use of metal matrix composites for its high specific strength/stiffness are in aerospace and automobile industry. Metal Matrices preferable for such applications are aluminum, magnesium and titanium. Another common use of metal matrix composites in high temperature structural applications are in places where high temperature mechanical properties are indispensable. Matrices commonly used in these applications are cobalt and cobalt-nickel. Particulate and discontinuous fiber reinforcements generally results in isotropic properties of the metal matrix composites. The use of continuous fiber reinforcements induce anisotropic properties of the final composites fabricated. The isotropic/anisotropic nature of composite properties is important consideration in structural applications.

Fig. 1 Heat dissipation path in Electronic Packaging.

Most common fabrication methods include solid-state methods (powder metallurgy route), liquid-state methods (squeeze casting, stir casting), semi solid-state methods and in situ fabrication techniques. Advancements in fabrication methods of metal matrix composites and nano reinforcements has expanded the use of these composites to several non-structural applications. The next generation of MMCs are not limited only to load bearing applications but extended to functional applications. MMCs can be designed to inbuilt specific native properties and can be used to perform functions like thermal management in electronic devices, self-repairing functions, self-lubricating functions, electrical and magnetic functions. This article gives a summarized review of applications of metal matrix composites in non-structural applications.

Non-Structural Applications

Thermal Management and Electronic Packaging

In almost all electronic/optoelectronic devices, not all the energy consumed by these devices is converted into useful work. In case of a computer, only a percentage of the electrical energy consumed by it get converted into computing work, light, sound, transmission radio waves and chemical energy in battery. Most of the electrical energy gets converted into heat. Heat sinks used in electronic devices are designed mainly for thermal management in electronic packaging by creating a heat dissipation path (refer [Fig. 1](#) and [Fig. 2](#)). In the past, heat sinks were made of traditional materials like copper, aluminum, copper-molybdenum alloy or copper-tungsten alloy. The ever-increasing density of packaging density and integration level of electronic devices greatly increase the amount of generated waste heat in a small space. The materials used traditionally in heat sinks does not provide efficient thermal management for devices with higher packaging density, low weight and stringent reliability considerations ([Zweben, 1992](#)). Electronic devices with high packaging density demands heatsink with excellent thermal conductivity, thermal expansion coefficient, which matches with that of the electronic component it supports. Novel composite materials has contributed to the improvement of the efficiency of heat sinks.

Metal matrix composites with copper and aluminum as matrices are preferable for heat sink materials. The reason for this is twofold: the thermal conductivity of Al or Cu Matrix composites can be improved by reinforcements with high thermal conductivity and versatility of controlling the coefficient of thermal expansion by adjusting the weight fraction/volume fraction of the reinforcement material. The reinforcements that are used for such heat sink applications are carbon, SiC and diamond either in the form of particles or fibers ([Zweben, 2005](#)). Aluminum matrix based composites are exceptional for thermal management applications because of its low specific weight and high specific thermal conductivity.

Due to low weight and high performance, SiC reinforced aluminum matrix composites has been selected for electronic packaging application in highly demanding avionics industry. With 75% volume fraction of SiC reinforcement, the aluminum matrix composites exhibits low coefficient of thermal expansion ($6-7 \times 10^{-6} \text{ K}^{-1}$) and low density (about 3 g/cm^3) ([Sarno, 2001](#)). However, thermal conductivity of SiC reinforced aluminum matrix composite is not so high to be suitable for high-end applications. Application of SiC/Al particulate composite is limited due to issues in brazing during electronic packaging processes. The brazing temperature of the composite should be in the range of $450-550^\circ\text{C}$ to avoid melting and degradation of mechanical properties. There is a lack of suitable filler metals for brazing in such a temperature range ([QU et al., 2011](#)).

In order to increase the thermal conductivity of aluminum matrix composites, carbon or diamond reinforcements are employed. Diamond reinforcement results in extremely high thermal conductivity where as carbon reinforcement results in a composite with less difficulty in machining ([QU et al., 2011](#)). Typically, these composites are fabricated by liquid infiltration method or powder metallurgy process. Diamond/copper composite with isotropic thermal diffusivity fabricated through high pressure sintering technology was found to have overcome the processing problems faced in the past such as low wettability and unfavorable interfacial reactivity ([Yoshida and Morigami, 2004](#)). $\text{Ba}_{0.7}\text{Sr}_{0.3}\text{TiO}_3$ nanoparticles reinforced copper matrix composites have been investigated to have exhibited remarkable thermal conductivity (293 W/mK) when compared to SiC reinforced aluminum matrix composites. This novel nanocomposite also has coefficient of thermal expansion, which is matching with GaAs and Si making it a highly assuring material for heat sink application in electronic packaging ([Sanjay et al., 2019](#)).

Application in Microprocessor Lids and Carrier Plates for Power Modules

Thermal management is increasingly inevitable in new generation of microprocessor assemblies with high clock speeds and device density. The thermal management solution include a lid or heat spreader. The lid keep contact with the microprocessor and transfer the heat from the packaging assembly (refer [Fig. 3](#)). AlSiC microprocessor lids are preferred as they meet the demands of

Fig. 2 Heat Sinks in Electronic/Optoelectronic Devices.

light weight, high thermal conductivity, dimensional stability and matching coefficient of thermal expansion with microprocessor assembly (Occhionero and Adams, 2005).

SiC reinforced Aluminum matrix composites are used in carrier/base plate substrates in medical power supply applications and IGBT modules. The traditional power substrate material, copper was replaced by AlSiC composites. The composites offers matching coefficient of thermal expansion which ensures reliability of the device and high thermal conductivity. AlSiC composites also withstand thousands of cyclic thermal stresses without cracking or delamination generated between the dielectric substrates or IC devices (Occhionero *et al.*, 2002). These composites do not require interface layers to get attached to the device substrate and enable direct attachment with substrate materials. This is possible because the coefficient of the thermal expansion of these composites can be adjusted to match with that of the substrate. If the coefficient of thermal expansion of the carrier plates does not match with that of the substrate, then an additional interface layer is required to compensate the thermal stress, which in turn increases the thermal resistance of the system. The fabrication process of this AlSiC is a near net shape process which produces near exact product geometry with threads and holes. This near net shape fabrication provides tight tolerances, cost effectiveness as it delivers high yields, and eliminates costly machining processes. Integration with cooling tubes or very high thermal conductivity insert is possible because of the unique casting processes.

Self-Lubricating Applications of MMCs

To increase the efficiency of the heat dissipation between two relatively moving components and to reduce the energy consumption of such moving parts, new tribological materials have been developed. There have been several strategies to improve the tribological properties of metals. Surface modification, alloying, reinforcements, modification of morphology are some of the strategies to incorporate excellent tribological characteristics in metal. In recent times, self-lubricating reinforcements were developed which removes the needs of external lubricating fluids. Metal matrix composites, fabricated by reinforcing graphite particles, offer self-lubricating property along with excellent wear resistance (refer Fig. 4). They eliminate the requirement of an external lubricant and reduce the coefficient of friction between the moving parts. Graphite is a well-known lubricant and graphite reinforced MMCs offers self-lubricating properties. Such composite systems has the ability to create a thin film of lubricating material, which acts as micro self-lubricating layer. In graphite reinforced MMCs, graphite micro-particles transferred between the contact surfaces function as solid lubricant.

One of the demerits of micron size graphite reinforced aluminum metal matrix composites is that it tend to degrade the mechanical properties. Hardness of graphite reinforced aluminum metal matrix composite has been found to decrease with increase in the graphite content although coefficient of friction and wear rate decrease. Sometimes the mechanical properties of graphite reinforced aluminum matrix composites drop below the mechanical properties of the unreinforced aluminum alloy. This deficiency can be overcome by the development of hybrid composites by adding ceramic particles in graphite reinforced aluminum matrix composites. The hard ceramic particles in this hybrid composite improve its mechanical properties such as hardness whereas the graphite particles in the hybrid composite enhance the self-lubricating properties. Hybrid aluminum matrix composites containing 1 wt% graphite and 10 wt% SiC ceramic particles reduced the wear rate by half that of the wear rate observed in unreinforced aluminum. The mechanical properties of the hybrid Al matrix composites are almost equal to the unreinforced Al alloy. Graphite reinforced Al matrix composites have already been used in automobile cylinder liners due to its self-lubricating properties.

An alternative to the hybrid composite system is composite with single reinforcement, either carbon nano tubes (CNT) or graphene. Graphene and CNT are alternative forms of graphite. Graphene reinforced composites exhibit better mechanical and tribological properties but they post difficulties in fabrication using conventional techniques as well as increase in cost.

Graphite reinforced copper matrix composites show excellent lubrication properties as well as machinability. This type of copper matrix composites replaces lead copper composites, which are banned due to its toxic nature of lead. So lead free copper composite reinforced by graphite has potential to be used in bearing application. The graphite particles in bearing component can be selectively concentrated in the internal periphery to create a graphite rich zone. This creates a surface abundant with graphite particles and the bulk of the component remains unaffected.

Bronze matrix composites reinforced with silver show self-lubricating properties when sliding against stainless steel. These composites were fabricated by powder metallurgy techniques and tested using tribotester in seawater environment. The silver in

Fig. 3 AMD Athlon II Microprocessor's Substrate & Microprocessor Lid (Adopted from Grabcad.com).

Fig. 4 Graphite plugged bearings and bushings (Adopted from cipcomposites.com).

the composites develops a self-lubricating layer over the worn out surfaces of the composite. Silver reinforcement of about 7 wt% in bronze has exhibited best tribological performance when compared to the monolithic bronze (Cui *et al.*, 2013). Self-lubricating composite coatings on metallic substrate also form the lubricating layer at the surface of the component. Some of the self-lubricating composite coatings developed were $\text{Al}_2\text{O}_3/\text{PTFE}$ (Wang *et al.*, 2010), $\text{NiCr}/\text{Cr}_3\text{C}_2\text{-WS}_2\text{-CaF}_2$ (Liu *et al.*, 2013), WS_2/CaF_2 (Zhang *et al.*, 2009) and MoS_2/Ti (Renevier *et al.*, 2001). These composite coatings eliminate reinforcement dispersion in bulk material and hence such coatings are easier to synthesize.

Self-Healing MMCs

Researchers and engineers are fascinated by the self-healing/self-repairing capabilities of biological systems and efforts are in place to mimic such biological systems. Self-healing is the technique of repairing cracks or damage in the material either autonomously or by influence of external stimulus. These are new class of materials recently developed. Significant successful research efforts in self-healing polymeric materials have been made. In case of metallic materials, due to its low rate of diffusion of metallic atoms and high bond strengths, it is much tougher to heal metals and alloys.

Customized heat treatments, reinforcing shape memory alloys wire and particles in the metal matrix are some of the techniques used to induce self-healing behavior to metal matrix composites. Shape memory alloy (SMA) particles or wires would remember their original shape and return back to their original shape after damage. If a metal matrix composite with SMA particles/wires are cracked, the composite is heated to its austenitic transformation temperature of the shape memory alloys, which alter the SMAs to revert back to its original shape thereby closing the crack formed in the composite.

The healing component of the composite material is generally hypereutectic or hypoeutectic composition. If such a composition is heated to above eutectic temperature, a combination of solid phase and liquid phase in equilibrium will be formed. Thus, the matrix would be molten at the heated temperature. This leads to fusion/welding of the crack during cooling. There is an optimal solid-liquid ratio for effective healing and it was found to be in the range of 20%–30% of the liquid phase. At this optimal solid-liquid ratio, the dendritic structure will be in stable solid state, while the liquid in the interdendritic regions flows freely thus closing the cracks. Self-healing composite materials are developed with Tin based bimetal as matrix and NiTi SMA fibers as reinforcement phase. Self-healing MMC systems have also been developed by embedding microcapsules in metal matrix of high melting temperature. The microcapsules contain a low melting alloy, which will break when cracks get propagated through these microcapsules. The broken microcapsules contained particles of low melting point. If the cracked material is heated until the low melting point material melts, then the melted material flows and fill the developing crack thus closing the crack and arresting the crack propagation (refer Fig. 5). Self-healing MMCs increases the reliability of the part, decreases the maintenance efforts and increases the life of the component.

Electrical Applications of MMCs

Aluminum exhibit higher electrical conductivity with density one third that of copper. Such excellent conductivity combined with lightweight and specific stiffness makes it the best choice for antenna and EMI Shield applications. Graphite fiber reinforced

Fig. 5 Mechanism of Crack Closure in Self Healing MMCs.

Aluminum matrix composites exhibit high electric conductance. Its excellent electrical properties made them possible to use in the construction of antenna spar with high gain for Hubble space telescope. This composite is fabricated by reinforcing graphite fibers (P100) in Aluminum alloy matrix (6061) by infiltration process. A preform containing 40% by volume graphite fibers (P100) was used in the infiltration process. This composite also functions as EMI shield (Rawal, 2001). This antenna spar is 3.6 m long and exhibits low coefficient of thermal expansion, which can be used to maintain the position of the antenna during maneuvers in space. This composite also provides electrical signal transmission between the antenna dish and spacecraft.

Magnetic Applications of MMCs

Aluminum is paramagnetic (weakly magnetic) and exhibits insignificant magnetic properties when subjected to intense magnetic field. Its magnetic properties can be improved by reinforcing it with suitable magnetic particles. If the magnetic particles are sufficiently hard, then reinforcing such magnetic particles in aluminum matrix will improve magnetic properties and mechanical properties of the matrix. CoFe_2O_4 nanoparticle is a high coercive magnetic particle, which is known for its magnetic property and its high hardness. It exhibits high chemical stability and moderate magnetic saturation. Magnetomechanical properties of aluminum metal matrix are improved by reinforcing it with this CoFe_2O_4 nanoparticle. These nanoparticles are synthesized sonchemically by reverse method of co-precipitation. The reinforcement of CoFe_2O_4 nanoparticle has led to significant improvement in magnetization value of aluminum metal matrix. The saturation magnetization value of aluminum matrix is 17.07 emu/g with 10 wt% of CoFe_2O_4 nanoparticle (Borgohain *et al.*, 2013). NiFe_2O_4 nanoparticles developed through citrate-nitrate route have been employed to improve the magnetic coercivity and magnetization value of pure aluminum metal (Maleki *et al.*, 2018). NiFe_2O_4 nanoparticles reinforced aluminum matrix composites have significantly improved magnetic properties compared to unreinforced pure aluminum.

Aluminum matrix composite with significant magnetic properties has an advantage over conventional iron based magnetic materials because of its low weight, higher ductility, high specific stiffness, high thermal conductivity and higher ease of manufacturing. Development of magnetic metal matrix composites with good magnetic properties without compromising the mechanical properties or with improvement of mechanical properties open new avenues of application of such composites. Engineering applications of magnetic metal matrix composites are development of sensitive measuring devices and novel fuel-efficient engineering devices for automobiles, ships and aircrafts.

Future Prospects and Challenges

The exploration of the novel non-structural applications of metal matrix composites has started recently by researchers and engineers. It is expected that the applications of metal matrix composites will grow enormously with customization of metal matrix composites to specific industries. With development of additive manufacturing, the fabrication process of these composites is expected to change in coming years.

Novel self-lubricating Aluminum matrix composites exhibit potential to mitigate fretting wear in mechanical assemblies encountering fretting motion. Fretting loading is a wear mechanism that occurs in a small amplitude oscillatory and/or radial relative motions between two contacting components in an assembly (Ali *et al.*, 2010, 2009). Fretting contact may combine with fatigue loading in assemblies where vibrations are dominant resulting in fretting fatigue (Ali and Raman, 2010). Nano silver particles can be reinforced in aluminum alloy to fabricate aluminum matrix composites with self-lubrication characteristics to be used in fretting wear situations. Silver particles may form a debris bed (third body) which reduce the fretting wear rate and cracking. Graphite and SiC reinforced aluminum also show potential to be used in aeronautical applications where self-lubrication can be used to resist fretting loading.

Other potential non-structural applications of MMCs are in electronic detectors in MRI/NMRI systems and in CT scanners.

MMCs have been investigated for its potential application in high precision space optics. Plasma thermal sprayed ceramic particle reinforced Al matrix composites (Jiang and Nikanpour (2000)), graphite-cyanate composites (Ozaki *et al.*, 1996), hybrid

carbon fiber reinforced SiC composites (Krödel and Tsuyoshi, 2007) have been evaluated for space mirrors and space optical telescopes. Future space optical mirrors and optical telescopes are expected to be these metal matrix composites.

Other challenges that affect the future applications of MMCs include,

- (1) Development of MMCs with higher ductility and fracture toughness
- (2) Understanding of microstructural development in MMCs
- (3) Need of reliable and low cost non-destructive inspection methods for MMCs
- (4) Developments of low cost and high quality reinforcements for MMCs
- (5) Development of reuse/recycling techniques for MMCs
- (6) Development of low cost secondary processing techniques for MMCs

Particulate Reinforced Polymer Matrix Composites

There are a wide variety of materials, structures and routes for the production of polymer composite materials ([Singh et al., 2021](#)). Particulate is a very common structure of reinforcement utilized within polymer matrix composites. There are many forms of particulate morphology and material type. In recent times, there has been a focus on the introduction of particulate reinforcement within polymers that are additively manufactured, either within the feedstock preparation or during the feedstock deposition. As example of ABS filaments to be used for Fused Deposition Modeling with graphene reinforcement was presented in the work of [Singh and Kumar \(2021\)](#). The exfoliated graphene was mixed with ABS before extrusion into the reinforced filament which resulted in a filament with much great thermal conductivity of 7.6 W/mK. Higher mechanical properties are often sought from polymer matrix composites than can be achieved from the matrix material alone.

Fiber Reinforced Polymer Matrix Composites

Fiber reinforced polymer matrix composites are in particular used where very demanding physical properties are required. E-glass, S-glass, carbon, aramid and boron fiber are common fiber reinforcements and can be integrated within the polymer composite in many ways. One common method for composite fiber direction control is achieved through the use of laminated polymer composites. The range of polymer composite matrix and reinforcements as well as the effect of fiber orientation is presented by [Ghamarian et al. \(2021\)](#). In addition to traditional thermosets and thermoplastic polymers, rubber materials are also reinforced with particulate and fiber reinforcements. In the article from Irez et al., the reinforcement of epoxy-rubber with alumina fiber and boron nitride particulate was examined ([Irez et al., 2021](#)). The ability to produce such reinforced rubber materials could provide a long life and reuse of materials, providing at more environmentally friendly life cycle.

Biomedical Applications of Polymer Matrix Composites

The production of bone PMMA cements with various reinforcing agents is an area where there has been a lot of published research. Thermal, mechanical and biological properties are important considerations for such materials. Reinforcing agents include hydroxyapatite, carbon based nanomaterials, and chitosan. A review of the research in this area and resulting physical properties is presented in the article of [Bakhtiari et al. \(2021\)](#).

A detailed review of biopolymers matrix composites for medical applications is presented in the article of [Shariatnia \(2021\)](#). A range of biopolymers and their applications are presented. These include chitosan, carboxymethyl chitosan, alginate, hyaluronic acid, cellulose, carboxymethyl cellulose, hydroxyethyl cellulose, chondroitin sulfate, starch, carboxymethyl starch, zein, gelatin, gellan gum, acacia gum, guar gum, tamarind gum, xanthan gum composites, pectin, collagen and polyhydroxy butyrate composites. The biological and environmental advantages of these biopolymers over conventional fossil fuel based polymer composites are discussed in this article.

Hydrogel films are three dimensional crosslinked hydrophilic polymers which can absorb large amount of water without solubilizing or losing integrity due to their strong internal bonds. This allows them to be applied for wound healing. Hydrogel composites can be reinforced with biopolymers such as polysaccharides, proteins and peptides, natural gums, or synthetic polymers such as PVA, PVP, or non-organic materials as discussed by [Khan et al. \(2021\)](#).

A significant amount of research internationally is examining polymer matrix composites for organ reconstruction ([Syed et al., 2021](#)). In this work, thermoplastic, thermosets, elastomers, and resorbable polymers are used. Reinforcing elements include natural and synthetic fibers, which more common implants include bone, joints, and dental scaffolds.

Other Application Areas for Polymer Matrix Composites

Polymer matrix composites are used in water filtration applications. In the article from Ahmadzadeh and Mohammadi, carbon nanotubes (CNTs) and graphene oxide (GO) are discussed in terms of their ability to improve the adsorption capacity as well as mechanical, chemical and thermal resistance of the polymer composite ([Tofghy and Mohammadi, 2021](#)). Recent developments in water and wastewater treatment applications are reviewed in their article.

Another large sector area where polymer matrix composites are used is in the aerospace industry. In this case, high specific strength, good fracture resistance, and high damage thresholds are generally sought. The percentage of fiber reinforced polymers

used in the aerospace industry has been increasing in recent years due to their superior properties. Devaraju and Alagar present a detailed review of the latest developments in this area (Devaraju and Alagar, 2021).

New Materials and Processing Methods for Polymer Matrix Composites

As for the other composite materials, additive manufacturing has been applied increasingly in recent years for the manufacture of polymer matrix composites. The developments in this area is presented in detail by Bahksheshi *et al.* (2021). Methods presented include SLS, stereolithography, direct ink writing, binder jetting, and fused filament fabrication. Both natural and synthetic materials as applied to polymer matrix composite production via additive manufacturing and related applications are presented.

A range of new polymers and their applications is presented in the article by Liu (2021). Some unique discussion in this article includes that on the shape memory and self-healing materials, as well as the composite applications in electrochemical and gas barrier membranes.

The notion of a multi-functional polymer matrix composite is important in general for composite materials. Through this, it is meant that the reinforcing phase and matrix are stable well bound together, can act as a unique multi-purpose material, and can exhibit properties under different external stimuli (Mhaske *et al.*, 2021; Nyabadza *et al.*, 2021). Some examples of multi-functional composites are presented in this review including in applications of smart packaging, self-healing, drug delivery, batteries and sensing.

Introduction

Over the past decade, there was a surge of needs in the manufacturing industries for materials with an enhanced performance for enhanced tensile strength, stiffness, density and functionality. On top of that, such materials should not incur a high production cost with greater sustainability initiatives.

Conventional materials such as metal with a single element has limited applications. Polymer is, thus, a preferred alternative. More recently, polymer composite materials are named as one of the alternatives with enhanced properties ([Yashas Gowda *et al.*, 2018](#)). Polymer matrix composites (PMC) have two major phases – continuous phase and dispersed phase. The continuous phase consists of different types of organic polymers that serve as the matrix to bind the dispersed phase, usually reinforcing fibers, together for an efficient transfer of load between them. The matrix is important as it serves as a platform to distribute the fibers evenly throughout the structure. Therefore, the properties of PMC depend on the matrix, reinforcement and the interphase. The reinforcing fibers enable the enhanced properties such as fracture toughness, tensile strength and stiffness. PMCs may also show added advantages of ease of processing, lightweight, higher productivity, and in cost reduction. Different types of fillers and fibers can be incorporated into the polymer matrix to achieve different applications ([Cao *et al.*, 2008](#)).

The mechanical and physicochemical properties of PMC are affected by mainly but not limited to the types and relative proportions of matrix and reinforcement, the geometry of the reinforcement, and the nature of the interphase. In this article, we will first discuss the mechanical and physicochemical properties of PMC in general, following by a brief discussion of mechanical and physicochemical properties by types of PMC.

General Mechanical Properties of PMC

High Specific Strength and Specific Modulus

In general, PMC have improved specific strength and specific modulus compared to the conventional polymer. The specific strength is the ratio of strength and density while the specific modulus is the ratio of modulus and density, and the dimensions or units are both length. These parameters also explain the bearing capacity and stiffness properties of a material with a fixed weight. Materials with high specific strength and specific modulus are desired in many critical industries such as aerospace and construction. The comparisons of specific strength and modulus of several PMC with conventional materials such as steel and alloys are presented in [Table 1](#).

Composite materials with a high specific strength and specific modulus are often a result of the high-performance and low-density of reinforcing fibers. Therefore, it is not surprised to have carbon fiber/epoxy composites showing the highest specific strength and modulus.

Good Fatigue Resistance and High Damage Tolerance

Metallic materials with a moderate fatigue failure crack easily when a high load is applied. A strong adherence at the interface between fiber and matrix play an important role here to prevent crack of the PMC. The cracks in a material normally starts from the weak link of fibers and the damage continue to deepen before the final destruction is achieved. Carbon fiber matrix composite usually has a stronger fatigue resistance as compared to wood epoxy laminates and glass fiber polymer-matrix composites. The fatigue strength of conventional metallic materials the majority of materials lies between 30%–50% of tensile strength whereas the fatigue strength of carbon fiber composite material is typically higher recorded at 70%–80% of tensile strength. As a result, the propagation of cracks in PMC is slower compared to conventional metallic materials. This is then followed by a series of damaging events such as matrix cracking, interfacial debonding, fiber pull-out and fiber split or break before leading to the final destruction. When a small number of fibers fracture, the part of the load can be transferred via the matrix to the other fibers. This characteristic makes PMC more robust and not fracture easily within a short period. The fatigue resistance of a composite material depends on various factors such as the fiber lay-up configuration, geometry of the structure and temperature ([Tomioka *et al.*, 2011](#)).

Table 1 Specific strength and specific modulus of commonly used materials and PMC fiber composites

Materials	Density (g/cm ³)	Tensile strength (GPa)	Elastic modulus (10 ² GPa)	Specific strength (10 ⁶ cm)	Specific modulus (10 ⁸ cm)
Steel	7.80	1.03	2.10	1.30	2.70
Aluminum alloy	2.80	0.47	0.75	1.70	2.60
Titanium alloy	4.50	0.96	1.14	2.10	2.50
Glass fiber composite materials	2.00	1.06	0.40	5.30	2.00
Carbon fiber II/epoxy composite materials	1.45	1.50	1.40	10.30	9.70
Carbon fiber I/epoxy composite materials	1.60	1.07	2.40	6.70	15.00
Organic fiber/epoxy composites	1.40	1.40	0.80	1.00	5.70
Boron fiber/epoxy composites	2.10	1.38	2.10	6.60	10.00
Boron fiber/aluminum matrix composites	2.65	1.00	2.0	3.80	7.50

Good Damping Characteristics

Some materials such as rubber and polymers are well known of their viscoelastic behavior due to the molecular structure of the polymer chains. The shortfalls of these materials are the lack of stiffness and a low vibration damping. Normally, the viscous behavior of rubber and polymers is generally temperature dependant. The viscous behavior of these materials is particularly strong over a narrow temperature around the glass transition temperature. In contrast, the viscous behavior of PMC with ceramic and carbon is prominent over a wide temperature range. This property renders PMC to be a more stable alternative.

The matrix contributes to the viscous behavior of PMC while the fibers are responsible for the elasticity of PMC. An increased fiber volume fraction enhances the elasticity parameters such as storage modulus and loss modulus but decreases the loss tangent which indicates the viscous characteristic (Chua *et al.*, 2015). PMC also have a high natural frequency and low resonance due to the ability of the interface between the fiber and matrix to absorb vibrational energy. Hence, the structure of PMC can stop vibration in a short period of time when it happens. As a result, this characteristic of resistant to vibration contributes to a tough and solid structure of PMC which allows PMC to be applied in much wider fields.

High Instantaneous Temperature Resistance

Some PMC such as fiberfill reinforced plastic (FRP) has a high thermal resistance. The thermal conductivity of this PMC is reported to be only 1% of metal materials. Due to this reason, FRP can be applied in an area that requires materials with a high specific heat, melting heat and vaporization heat such as protective materials for a missile nose cone.

Superior Electric Insulation Performance

Beside thermal resistance, FRP also shows a good electric insulation property which can be used as high-frequency wave-transparent materials for a radome.

Good Friction Property

Carbon fibers have low friction coefficient and self-lubricating properties. Therefore, the related composite materials have good friction-resistance and antifriction properties.

Static Mechanical Property

Mechanical properties of PMC can be enhanced by increasing the continuous carbon fiber volume within the PMC. However, an excessive addition of continuous carbon fibers may reduce the mechanical properties due to an inadequate binding of the fibers by the polymer matrix when exceeding the maximum interface bonding capacity. He and Gao (2015) reported that when the continuous carbon fiber volume increases from 50 to 70 vol% in an epoxy based polymer matrix, the flexural properties of the PMC were enhanced. However, the flexural properties reduce when the continuous carbon fiber volume increases above 70 vol%.

The addition of discontinuous short carbon fibers to a polymer matrix increases the tensile modulus of the PMC provided that a strong fiber-matrix bonding is established. The addition of discontinuous short carbon fibers up to 10 wt% to poly (trimethylene terephthalate) was shown to increase the tensile strength of the PMC. Similar observation was obtained when discontinuous short carbon fibers were added to the thermoplastic liquid crystal copolymer that increases both tensile strength and modulus due to a

good bonding between matrix and fiber interface. Carbon fibers showed a more significant increase in tensile strength compared to synthetic graphite powders due to a different bonding strength (Keith *et al.*, 2007). On the other hand, the addition of discontinuous short carbon fibers to polyvinylidene fluoride decreases the tensile strength and ductility due to the poor bonding between fiber and matrix (Ram *et al.*, 2014).

The adherence between matrix and fiber does not just depend on the affinity of the fiber. The matrix plays an important role. For example, epoxy is known as an excellent adhesive that provide many adhesive sites for fibers to attach at. Fibers with oxygen functional group can easily react with epoxy to form bonds (Semoto *et al.*, 2013).

Mohanty and Srivastava (2015) has conducted a study to compare the impact of addition of short carbon fibers and short glass fibers to epoxy on the mechanical properties of the PMC formed. It was reported that short carbon fibers were more effective to enhance the mechanical properties of PMC than short glass fiber in terms of flexural strength, flexural modulus and Charpy impact energy. Dang *et al.* (2012) has investigated the effect of addition of copper-coated carbon fibers to epoxy. It was reported that the tensile strength and modulus increases with an increase of filler content up to 0.5 wt%. The mechanical properties were weakening with increasing filler content above the optimum value.

Song *et al.* (2016) has reported a study on addition of short carbon fibers to acrylonitrile-styrene-acrylate copolymer. The addition of the filler caused increase in tensile strength and flexural modulus with increasing of filler amount. The flexural strength and the flexural modulus have increased by a percentage of 122% and 464% respectively at 30 wt% carbon fibers addition. Geng *et al.* (2007) has studied the addition of silica nanoparticle (20 nm diameter at 10 wt%) to a short carbon fiber-bismaleimide matrix composite. The flexural strength, tensile strength, flexural modulus and tensile modulus have increased by a percentage of 12%, 6%, 5% and 11% respectively. On top of that, the storage modulus, loss tangent and glass transition temperature T_g have also reported an increase in value.

Carbon nanotube and carbon nanofiber (CNT/CNF) have also been used as reinforced fibers for polymers. CNT and CNF have good binding capability with polymer. The higher the amount of multi walled CNT (MWCNT), the higher the increase in tensile strength and tensile modulus of epoxy based matrix. The incorporation of MWCNT (10–25 nm diameter, 5–10 μm long, 0.3 vol%) to epoxy increases the tensile strength and compressive strength, interfacial shear strength (IFSS) for the interface between carbon fiber and epoxy (Wang and Li, 2016). Double walled CNT (DWCNT) have also been used to increase the fracture toughness of epoxy. Gojny *et al.* (2004) has incorporated amino-functionalized DWCNT (2.8-nm diameter, 0.1 wt%) to epoxy based polymer and the fracture toughness increases from 0.65 to 0.77 MPa but the effect on tensile strength and modulus is weak.

Subramaniam *et al.* (2016) has reported a study of using combination of short chain fibers and MWCNT as reinforced fibers in epoxy based matrix. The combination has recorded synergistic effect in relation to the tensile strength, fracture toughness, and impact strength. The synergistic effect is postulated as a result of the ability of MWCNT to promote plastic deformation of the epoxy matrix and decrease the stress concentration near the interface between the short carbon fibers and the epoxy matrix.

Carbon black can also be used as reinforced fiber in PMC. Carbon black (2–20 nm) has shown better results than MWCNT to enhance the tensile strength and ductility of a styrene butadiene matrix composite. In the study conducted by Tabačiarová *et al.* (2016), carbon black showed an increase in tensile strength by 1205% whereas MWCNT has increased tensile strength by 310%. On the other hand, carbon black has increased the tensile ductility from 300% to 860% but MWCNT has decreased the tensile ductility from 300% to 230%.

Environmental Degradation

Environmental degradation due to moisture, heat and ultraviolet is an important criteria of consideration for PMC used in critical industries. Carbon fiber enhanced epoxy matrix composite degrades under a normal hygrothermal pressure that results in a significant reduction of mechanical strength (Larbi *et al.*, 2015). The epoxy matrix can absorb moisture leading to an increased in the PMC volume and the contact electrical resistivity of the interlaminar interface of the laminate.

On the other hand, thermoplastic polymer based PMC are more resistant to moisture. The major disadvantage of this PMC is the UV degradation. Poly(ether-ketone-ketone) (PEKK) based PMC is a common example due to its high glass transition temperature, strong mechanical strength and fracture toughness, low moisture absorption and good environmental resistance. However, UV might accelerate weathering condition (Mazur *et al.*, 2014).

Recovery and Recycling of Fibers

Environmental friendly materials are desired in industry. Carbon fibers in the PMC can be recycled from cured or uncured scraps of epoxy-matrix composites by pyrolysis, followed by oxidative removal of any organic residual. The recovered fibers show similar properties to pure fibers.

On the other hand, there are also thermosetting matrices which cannot be recovered and recycled. These matrices have little value of reuse after cured. The process to recycle these PMC is tedious and it is unpractical economically. Researches have also been done on the reuse of scrap form of PMC. The scrap form of thermosetting PMC is found with little economical value. However, PMC with thermoplastic characteristics can be used in scrap form (Giorgini *et al.*, 2015).

Physicochemical Properties and Characterization Method of PMC

Infrared (IR) Spectroscopy Analysis

Infrared (IR) spectroscopy has gained widespread use as a crucial analytical technique to characterize PMC. The near IR region $4000\text{--}400\text{ cm}^{-1}$ ($2.5\text{--}25\text{ }\mu\text{m}$) is useful for applications in characterizing PMC. Spectra formation relies on the IR radiation absorption that gives rise to the molecular stretching and bending vibrations. Within the near IR region, there exists a fingerprint region ($1800\text{--}400\text{ cm}^{-1}$) containing multiple peaks of narrow line width but remains a strong identity for differentiation of molecular interactions. Fourier transform (FT) spectrometers is an instrumentation that allows a stronger signal-to-noise, rapid spectral acquisition and a better resolution than a typical dispersive spectrometer. The FT instrumentation can be found frequently to be combined with a technique called attenuated total reflection (ATR) spectrometry where multiple internal reflections can occur at the interface between the sample and ATR crystals of high refractive index (such as zinc selenide, germanium and diamond). This technique also generates an evanescent wave which allows the penetration of the IR beam into the sample and this shows an excellent signal-to-noise ratio. Moreover, this analysis requires very minimum or no sample preparation but good contact is required between the sample and the ATR crystal. Eibl (2017) compared bench-top and hand held IR spectrometers as well as ATR and diffuse reflectance (DR) methods in the investigation of thermal damage on the epoxy matrix with carbon fibers. The results from bench-top and hand held IR spectrometers are comparable. But DR methods are preferred for bulk material owing to the difficulty in predicting the duration and temperature of the thermal pre-load for the bulk ATR method.

FTIR spectroscopy is a non-invasive technique that identifies the components in PMC and measures interactions between the components. This analysis was utilized by Cecen *et al.* (2008) in showing the interaction between reinforcing fibers in epoxy- and polyester-based composites synthesized via solution method using vacuum-assisted resin transfer molding (VARTM). An interaction between fibers and resin was seen due to the shift of OH stretching vibrations of epoxy (3364 cm^{-1}) and polyester (3448 cm^{-1}) to a lower wavenumber. With an additional new band at 2360 cm^{-1} for carbon/epoxy composites, it was shown that the interaction between carbon fiber and epoxy resin is stronger than the counterparts with glass fibers. Reinforcement of composites comprising of polylactic acid (PLA), sisal fibers (SF) and a commercial grade epoxy-functionalized oligomer Joncryl ADR[®]-4368 (ADR) by the addition of poly (butylene-adipate-terephthalate) (PBAT) resin was noted with an increased intensity of C = O stretching vibrations (1735 cm^{-1}) (Wu and Hao, 2019). FTIR analysis in different spectral ranges was followed by Agrebi *et al.* (2019) to understand the degree of reinforcement of a nanocomposite of natural rubber by the addition of cellulose nanoparticles. Apart from identifying molecular interactions of added materials into PMC, FTIR analysis was demonstrated by Tonetto *et al.* (2013) to confirm the conversion of resin cements, a dental PMC, under light curing. The C = C stretching vibrations (1638 cm^{-1}) were monitored in relative to the aromatic C–C (1608 cm^{-1}) before and after the curing process. In addition, FTIR spectroscopy was used to perform surface characterization of silanised lignocellulose fibers reinforced with epoxidised natural rubber/poly-lactide (ENR/PLA) composites (Masek *et al.*, 2016). The intensity of epoxide groups (C–O–C) of ENR at 1248 and 880 cm^{-1} was greatly reduced indicating the reaction of oxirane ring of ENR with amine group of silane from silanised lignocellulose fibers.

Chemometric analysis such as principal component regression (PCR) and related technique, principal component analysis (PCA) can be applied to identify subtle changes in large datasets of IR spectra. The use of multivariate data analysis in deconvoluting FTIR data has been applied to investigate thermal degradation or incipient thermal damage of PMC such as carbon fiber reinforced bismaleimide resins (Toivola *et al.*, 2018) and carbon fiber reinforced epoxy system including HexPly[®] 8552/IM7 and HexPly[®] M18-1/G939 (Eibl, 2017; Eibl and Wolfrum, 2012; Wolfrum *et al.*, 2016). Particularly, this spectral analysis provides an accurate estimation for the duration and temperature of a thermal pre-load for PMC. Toivola *et al.* (2018) achieved the differentiation of the interlaminar shear strength (ILSS) carbon fiber-bismaleimide composites over a temperature range by using multivariate analysis of the first derivative of absorbance spectra (Fig. 1). It is well recognized that the differences in the IR diffuse reflectance spectra of the samples are hardly identified after thermal exposure at different temperatures (Fig. 1(a)). The first three principal components explained more than 95% of the total variation in the spectra (Fig. 2). The regression coefficients (RCs) were used by the model to relate the identified principal components of the ILSS of the composites. Several peaks reported in the first principal components including 1188 , 1374 , 1556 , and 1712 cm^{-1} are associated with functional groups that participate in important thermal exposure reactions. The correlation between PCR calibration model and the ILSS of the samples shows an excellent linear regression (Fig. 3(a)). The horizontal dashed line in Fig. 3(b) indicates that this model predicts statistically significant differences in ILSS after 232°C exposure. Comparing to the physical damage evaluated by ultrasonic testing (UT), the vertical dashed line shows that the detection threshold of physical damage happens between 316 and 330°C . The model used can improve the detection of ILSS loss (chemical damage) by more than 75°C as compared with UT. This also explains that thermal damage causes the loss of $\sim 50\%$ of the original ILSS which is not detected previously by UT.

Morphological Properties by Scanning Electron Microscopy

Microscopy, usually minimally or non-destructive, provides a rapid analysis of a small amount of sample for morphologic properties including size and shape. Owing to a higher magnification and resolution than normal light microscope, scanning electron microscopy (SEM) is a frequently used morphological analysis method that employs the scanning with an electron beam. For samples that are not electrically conductive, a thin coating of metal such as gold or platinum is applied. SEM results are supportive evidences to the findings from other analyses such as mechanical test and FTIR spectroscopy.

Fig. 1 (a) IR diffuse reflectance spectra for carbon fiber-bismaleimide resin laminate ILSS samples after thermal exposures. (b) Gap 1st derivative of IR diffuse reflectance spectra after thermal exposures. Adapted from Toivola, R., Afkhami, F., Baker, S., McClure, J., Flinn, B.D., 2018. Detection of incipient thermal damage in carbon fiber-bismaleimide composites using hand-held FTIR. *Polymer Testing* 69, 490–498.

SEM is commonly used to observe distribution of reinforcing materials in PMC. Yunus and Alsoufi (2018) observed a homogeneous distribution of bioceramic fillers such as titanium oxide (TiO₂) and alumina (Al₂O₃) in the hybrid polymer matrix composites with high-density polyethylene (HDPE) with SEM image analysis. Apart from analysing the distribution of reinforcing materials in the matrix, SEM has also been used to examine interfacial failure or adhesion of PMC during fracture. Considering that added fibers are tightly connected with the matrix or underlain the matrix, they tend to be broken and torn up in the composites. Cecen *et al.* (2008) reported that poor fiber/matrix adhesion is observed in polyester composites with carbon and glass fiber due to extensive damage. The clean fiber surfaces on epoxy-based composite reinforced with glass fiber reflect extensive interfacial failure. The fibers are loosely held by the matrix material after failure. However, epoxy composites demonstrated considerable matrix failure together with the carbon fibers, indicating a good interfacial adhesion. In recent study by Latief *et al.* (2019), the addition of 5% alumina particles was found to strengthen polyester composites as indicated by a morphological change from the unreinforced composites. However, the presence of 10% alumina particles promoted the formation of voids and agglomeration in the SEM images.

Wu and Hao (2019) observed the reinforcement of polylactic acid (PLA)/sisal fibers (SF) composites by incorporating a commercial grade epoxy-functionalized oligomer Joncryl ADR[®]-4368 (ADR) and poly (butylene-adipate-terephthalate) (PBAT) resin. SEM images revealed that part of the polymer matrix concentrated on the sisal fiber surface and welded to the PLA matrix to

form a self-welded fiber structure in PLA/PBAT/SF/ADR composites. Many broken fibers in the tensile fracture as shown in the SEM images suggested that ADR improves the interfacial interaction between fibers and polymer matrix, as well as between PLA and PBAT. Likewise, Oladele *et al.* (2020) observed a smoother surface for treated palm kernel shell fiber (PKSF) and particulate cassava peel (PCP) hybrid reinforced epoxy composites than the untreated one (Fig. 4). SEM micrograph of the untreated composites showed more particles at the fractured surface, indicating weak interfacial reaction and bonding between the untreated fiber and the epoxy matrix.

Energy dispersive X-ray spectroscopy (EDX), a rapid and non-invasive technique, has been used to complement SEM analysis through elemental characterization of composites chemical compositions. X ray emission from elements are dispersed based on the emission energies into separate channels that are expressed as peaks in a EDX spectrum. The number of peaks appeared for an individual element relies on the complexity of the electronic structure. Usually, heavier elements with more electron shells produce more emission peaks and complicated spectra. Therefore, EDX can be used for both qualitative and quantitative analyses. Moreover, EDX can provide a mapping of the spatial distribution of certain elements on a SEM micrograph. However, the penetration of X ray beam into the sample may excite the areas below the surface that are not shown in the SEM image. This may produce misleading results of EDX analysis.

Apart from a rough surface and an homogenous dispersion of reinforced particles observed in SEM micrographs, EDX characterization was employed by Akaluzia *et al.* (2021) to show an increase in the contents of calcium, silicon, potassium and aluminum in the polyester matrix reinforced by hardwood charcoal particles (Fig. 5).

Fig. 6 Bragg's law and diffraction.

X-Ray Diffraction Analysis

X-ray diffraction (XRD) analysis gains attention in the characterization of PMC to reveal the information of crystallinity and structural conformation of materials. XRD works based on the principle of elastic collisions between the incoming X ray beam and a particle that cause scattering of the reflected beam in all directions. The scattering pattern appears as peaks due to the constructive interference of the reflected beam along certain angles. This simple scattering can be explained by Bragg's law as shown in Fig. 6 (Bragg, 1913) and expressed by the following equation:

$$n\lambda = 2d\sin\theta$$

where n is any integer, λ is wavelength, d is the vector representing the displacement between reflection sites and θ is the angle between the reflected wave and the plane formed by the material's surface. XRD is an accurate and non-destructive analysis that requires only minimal amounts of sample and sample preparation (Schnablegger and Singh, 2011).

X-ray structural investigations can be performed at different approaches depending on the diffraction angles. The typical XRD or wide angle X-ray scattering (WAXS) has a shorter distance between the sample and detector, allowing diffraction measurements at a larger angle. While small angle X-ray scattering (SAXS) allows the detection of scattered X rays at a low angle which is beneficial for sample with large structural units (structure features with large repeat distances).

XRD analysis can be used to detect the presence of materials through identification of the fingerprints of the spectrum. Latief *et al.* (2019) confirmed the addition of alumina particles to the polyester matrix via the strong alumina peaks present in the XRD diffractograms. XRD data was used by Mahendran *et al.* (2016) to confirm the incorporation of graphene oxide sheets in the poly(vinyl alcohol (PVA)/poly-2-acrylamido-2-methyl-1-propanesulfonic acid (PAMPS)/GO composites.

In addition, XRD analysis has been used to determine the crystallinity of composites because the degree of crystallinity can affect the mechanical properties of composites. Spahr and Schultz (1990) determine the degree of crystallinity in the poly(aryl-ether-ether-ketone) matrix-carbon fiber composites using WAXS. Volkova and Kalistratova (2015) examined the loss of crystallinity of polytetrafluoroethylene (PTFE) composites with carbon fiber, bronze and molybdenum disulfide at a temperature more than 555K. This is indicated in the disappearance of peaks in the XRD diffraction spectrum. Apart from observing the degree of crystallinity, Caban and Nitkiewicz (2007) revealed the polymorphic behavior of polypropylene in the glass fiber-polypropylene composites using both SAXS and XRD analyses. XRD spectrum revealed the polymorphous α types (monoclinic) or β (hexagonal) of polypropylene and polypropylene smectic phase (amorphous) in the composites. Also, glass fibers was seen to reduce the crystallinity degree of the polymeric matrix. In another study, Chethan *et al.* (2018) reported the changing of α to β phase of polyvinylidene fluoride (PVDF) matrix in the XRD diffractograms when nickel coated multi-walled carbon nanotubes (Ni-MWNT) and graphitized carbon nanofibers (GCNF) were added as nanofillers. This result supported the findings of IR spectroscopic and thermal analysis.

Thermal Analysis

Differential scanning calorimetry (DSC) is a common thermal analysis to investigate the thermal behavior of a sample. The basic principle of DSC works by measuring the temperature difference between a sample and a reference during heating, cooling or holding isothermally. By applying a heat signal to a sample, the response is measured as energy changes of thermal events such as melting, crystallization, glass transition and degradation over a temperature range or time period. Similar to FTIR analysis, thermal characterization using DSC requires minimal or no sample preparation and quick measurement can be done easily with a small quantity of sample. However, this technique is a destructive analysis.

In general, there are two types of DSC instruments: power compensation and heat flux. Power compensation DSC has two separate furnaces for the sample and reference with a temperature sensor placed in a bridge circuit. The temperature difference between these two furnaces is maintained at zero or near-zero through an electrical supply to the sample furnace at a different power. On the other hand, heat flux DSC has both sample and reference pans placed symmetrically within a furnace with a thermocouple in close contact with each pan. This design has a similar heat flow from the furnace to the sample and reference. This type of DSC is more commonly found.

Fig. 7 DSC thermograms of semi-crystalline polymers.

The heat flow (dQ/dt) from each pan is represented by the equation below.

$$\frac{dQ}{dt} = \frac{\Delta T}{R}$$

where Q is the heat, t is the time, ΔT is the temperature difference between the furnace and the pan and R is the thermal resistance of the heat path between the furnace and the pan.

The heat flow signal is determined by the heat capacity (C_p) involved during heating. Heat capacity is the energy required to raise the temperature of the sample by one degree in temperature. The equation for the DSC signal may be expressed by

$$\frac{dQ}{dt} = C_p \frac{dT}{dt}$$

Therefore, heat flow into the sample (endotherms) or out of the sample (exotherms) as a function of temperature or time is presented in DSC thermograms in the unit of mW. Thermal transitions are shown usually as peaks (e.g., melting) or steps in the baseline (e.g., glass transition). The data shown in DSC thermograms have the direction of heat flow with either endotherms or exotherms up.

Fig. 7 shows a typical DSC thermogram of thermoplastic semi-crystalline polymers such as polyvinyl chloride, polypropylene and PEEK commonly used in PMC. On heating, temperature increases at a constant rate. The crystalline structure breaks down when melting occurs and a change in its heat capacity is observed. This causes the formation of a large melting endotherm. In a semi-crystalline polymer, there is a portion of the polymer available in the amorphous form. This gives rise to glass transition (T_g) which does not involve a latent heat. The T_g is a baseline shift transition where the polymer chains become plastic or rubbery. An exotherm above the T_g may occur indicating the crystallization, especially when crystallization does not happen in its maximum capacity during cooling.

The addition of Ni-MWNT and GCNF as nanofillers in PVDF matrices increases both melting point (heating scan) and crystallization rate (cooling scan) of the polymer (Chethan *et al.*, 2018). This suggested a higher thermal stability of the composites.

Apart from its frequent use in determining melting and glass transition temperatures, DSC can be used to deduce the crystallinity behavior and the interaction of the components in the PMC which are closely related to the mechanical properties of PMC. The crystallinity of epoxy composites was found reduced when curaura fibers are added into the matrix (Barcelos *et al.*, 2016). The decreased crystallinity was observed in the reduction of melting endotherm of epoxy at 138°C, indicating the transformation of crystalline epoxy matrix into amorphous state due to the presence of curaura fibers.

Rubab *et al.* (2014) studied the curing behavior of epoxy-titania composite using DSC analysis. A complete crosslinking of epoxide groups with the amine monomers during curing process was indicated by a shift of glass transition from below zero to above 40°C. This also showed that the movement of polymer chains are restricted at the T_g temperature below 0°C.

DSC analysis may be accompanied by thermogravimetric analysis (TGA). TGA measures the weight change of a sample as a function of time or temperature. This analytical method is invasive but straightforward which is usually used to determine thermal and oxidative stability of a PMC. The weight changes are presented in the percentage of weight loss in typical TGA curve and first derivative trace or DTG can provide a better visualization of the data.

TGA allows empirical differentiation of the thermal load in thermal degradation of PMC, especially with an intermediate thermal damage or a rapid heat-up when thermal equilibrium is not reached within the matrix (Eibl, 2017). The same study also employed chemometric analysis to estimate residual strength and to predict duration and temperature of a thermal pre-load using TGA but less accurate prediction than IR spectroscopy. In addition, TGA showed the stability of PVA/PAMPS/GO composites up to 170°C and identified three major mass losses that accounted for the materials present in the composites (Mahendran *et al.*, 2016).

Mechanical and Physicochemical Properties of PMC by Types

Polypropylene (PP) Based Composites

PP based PMC have good mechanical properties, moderate dimensional stability, high temperature of thermal deformation and flame resistance. Furthermore, PP based PMC can be recycled. The recovered PP shows a higher density, a lower porosity and a high water absorption property with a high dimensional stability in comparisons to the composites and native PP (Shubhra *et al.*, 2011). Haydar and Beg (2014) has developed a coir-fiber-reinforced PP based unidirectional composites using compression molding method. The PMC has shown better mechanical properties in terms of tensile strength, tensile modulus and impact strength of the unidirectional composites, especially with a higher fiber loading until the optimum loading, thereafter the mechanical properties reduced with higher fiber loading. The optimum loading reported is 30 wt% coir. The coir-fiber reinforced PP based PMC was treated with tetramethoxy orthosilicate to improve the adherence of matrices and reinforced fiber (Haydar and Beg, 2014).

Polyethylene (PE) Based Composites

The incorporation of maize fibers into PE based composite such as HDPE can improve the thermal and mechanical properties of PMC by decreasing the thermal diffusivity and thermal conductivity (Trigui *et al.*, 2013). HDPE incorporated with hybridized kenaf and pineapple leaf fibers (PALF) have also been reported to provide a higher tensile strength and Young's modulus compared to HDPE with kenaf leaf fibers alone. This is due to a higher cellulose content of the hybridized fibers even though kenaf fibers was reported to improve impact and water absorption properties of the PMC. By hybridization of both fibers, the PMC can enjoy the combination improvement in mechanical and water absorption property (Aji *et al.*, 2012). Another study by Chollakup *et al.* (2011) revealed that longer PALF showed a higher tensile strength of the HDPE based PMC than shorter PALF due to an increased interfacial bonding and a more homogenous dispersion of long PALF. Bagasse fibers have also been used as reinforced fibers in both low density polyethylene (LDPE) and HDPE based PMC. When the bagasse fiber amount exceeds 50% in LDPE and HDPE, a reduction in mechanical and physical properties of the PMC was observed (Youssef *et al.*, 2009).

Polystyrene (PS) Based Composites

Sugar palm fibers have been used as reinforced fibers in PS based composites. Sapuan and Bachtiar (2012) has compared the impact of incorporation of five different weight percentages (10–50 wt%) of sugar palm fiber into PS using melt mixer and hot press. The results showed that higher sugar palm fiber contents resulted in higher tensile strength and Young's modulus of the high impact PS.

Polyvinyl Chloride (PVC) Based Composites

PVC is a common and high demand material in construction sector due to its compatibility with most natural fibers, low cost, high durability, chemical and flame resistance. Coconut fiber reinforced PVC/acrylonitrile styrene acrylate blends have been developed and the composite showed a higher impact strength and thermal properties with increasing of fiber content (Jiang and Kamdem, 2004).

Polyesters Based Composites

Polyester/natural fiber (banana/sisal) reinforced with hybrid pineapple leaf fiber and glass fiber were developed and compared. The two samples were evaluated for a constant total fiber loading 0.40 V_f by verifying the ratio of reinforced fiber. It was reported that the chemical treatment of the reinforced fiber showed a reduction in composite thermal contact resistance. (Idicula *et al.*, 2006). Sisal-jute-glass reinforced polyester composites have been developed. The study showed improvement in mechanical properties such as tensile strength, flexural strength, and impact strength. The result suggested that Sisal-jute-glass reinforced polyester composites can be used as alternate material to replace pure glass (Ramesh *et al.*, 2013).

A biodegradable aliphatic polyester reinforced with bagasses treated with 1%–5% sodium hydroxide and 1% acetic acid solution have been developed and characterized. The PMC showed improved flexural, impact and water absorption properties when the reinforced fibers were used in the range of 0%–20% v/v. The PMC serves as an alternative to replace the original polyester fiber (Cao *et al.*, 2006).

Epoxy Based Composites

Epoxy is a common polymer used in lamination, adhesives, coatings, and advanced composite surfaces due to the excellent mechanical and chemical properties, corrosion resistance, good thermal and dimensional stability (Ren *et al.*, 2008). Hybridization of epoxy composite with oil palm empty fruit branch (EFB)/jute fibers demonstrated better mechanical and flexural strengths than the untreated composites (Jawaid *et al.*, 2011a,b). The use of natural fibers such as EFB/jute fibers into reinforced

composites also reduces the environmental waste. The tensile properties of these hybrid composites showed increase in jute fiber content imparted higher strength than the oil palm–epoxy composites.

Conclusion

The blending of different polymer matrices with a variation of reinforcing fibers have brought tremendous significant improvements in the mechanical and physicochemical properties of PMC. Improvement in the properties is due to the reinforcement contributed by the reinforced fiber content. This overview has provided an insight on the general mechanical and physicochemical properties of PMC by giving examples of various types of PMC. Improvement of the mechanical properties such as strength, stiffness and impact strength has produced newer materials for the advancement in industry. The polymer matrix composites have several advantages, such as low cost, low density and lesser abrasiveness. More research is required to explore the scope and limitations of these materials.

Introduction

The word 'polymer' is the combination of two Greek words 'poly' and 'mers'. 'Poly' means many and 'mers' means parts. 'Mers' are the basic entity of polymer and when they link in the repetition they form a large molecule which is called polymer. Depending upon the types of 'mers' the polymer can be classified in many categories from the nature of polymer *i.e.*, natural or synthetic, thermoset or thermoplastic, polymer structure, its thermal behaviour, polymerization, and its preparative techniques [1].

The choice of individual polymer from the family of polymers for a particular application is difficult. Material properties, which are required, for particular application make it easy to choose a particular material. Moreover, the suitable processing technique for a particular application also help to choose a suitable polymeric material. The manufacturing technique to produce a part is chosen with respect to part design, low manufacturing cost and the type of the material to be used for that particular application from the family of polymeric materials. Number of processing techniques have been invented with their own advantages, disadvantages and applications [2].

Polymer materials and their composites have numerous applications due to their advantages over conventional materials [3,4]. Simple fabrication methods and low cost have made polymer matrix composites very popular. However, the use of polymers in comparison to polymer matrix composites as structural materials is very limited due to the difference of their mechanical properties. Composite materials have two phases, namely matrix and reinforcement. The different type of reinforcements are embedded into matrix in order to improve its properties with respect to its end use requirements. The applications of polymer matrix composites are mainly due to its high specific strength and specific modulus [5]. The applications of polymers matrix composites in the aerospace, marine and automotive industries are increasing day by day due to its properties such as low density, high specific strength, high specific stiffness, and high fracture resistance [6]. Whereas, the property of good corrosion resistance and chemically inertness not only make it suitable for marine boat bodies but also for chemical storage tanks, pipes as well as pressure vessels [7]. The applications of polymer matrix composites are attaining wide acceptance in the manufacturing of bridges due to lower weight, good fatigue impact and corrosion resistance of material [8]. Polymer matrix composite materials are the insulators and due to this property these are used in electrical appliances such as panels, housing and connectors [9]. All these properties also make it suitable for the biomedical applications [10].

Although there are number of parameters in polymer composite materials which influence their final properties but the change in material and the processing techniques are the most important ones. The processing techniques used to manufacture the polymer composites have many different variables which need to be controlled simultaneously to improve the performance of the material significantly. The optimization of different variables is crucial to enhance the properties of the composite in comparison to its parent materials [11]. Moreover, the part performance can be improved by the combination of two or more processing techniques together [12].

Besides shapes of the part, the choice of manufacturing processes depends upon type of material to be processed for a particular application. Polymers are broadly classified into two categories that is thermoplastic and thermosets. The processing techniques for both the materials are different and processing parameters are chosen and controlled accordingly. Table 1 shows the variability in different parameters for different types of materials.

Thermoplastic polymers have linear or branched chain molecules having strong intramolecular bonds but weak bonds between adjacent chains. They could be amorphous or semi crystalline in nature and can be processed by heating and pressing into desired shape. The advantage of these materials is that it can be easily reshaped under the effect of heat and pressure. On the other hand thermosetting polymers consists of cross-linked or three dimensional network structure with covalent bonds within all chains. Thermosets are formed by melting and then pouring into the mold to make a desired shape. Once they solidifies and they form 3-dimensional structure they cannot be reshaped. They decompose upon heating but do not soften [13]. The recycling property of thermoplastic materials has made it advantageous over the thermosetting materials [14]. However, as shown in Table 1, use temperature and solvent resistance of thermoset materials is more than that of thermoplastic materials. Since, the number of parameters need to be controlled while the manufacturing of composites with thermoset or thermoplastic matrix, fabrication of composites is a complex process.

Curing plays a very important role in the manufacturing of the component. Although curing of material depends upon many parameters, temperature and pressure for a particular time are the important parameters to be controlled for the transformation of resin (thermoset polymer) into final parts. Temperature initiates the chemical reaction and pressure force is used to flow the resin. The magnitude and duration of these process variables have a significant effect on the performance of the part to be produced for

Table 1 Comparison of characteristics of thermoplastic and thermoset polymers

Resin type	Process temperature	Process time	Use temperature	Solvent resistance	Toughness
Thermoset	Low	High	High	High	Low
Toughened thermoset	↑	↓	↑	↑	↓
Lightly crosslinked thermoplastic	High	Low	Low	Low	High

structural applications. Since duration is the integral part of the cure cycle and it also defines the rate of production, the shortest cure cycle will increase production rate. In the processing of polymers and polymer matrix composites, resin is converted into matrix and cure cycle is associated with polymer or resin behaviour such as viscosity, resin flow, consolidation, degree of flow etc. Differential scanning calorimeter (DSC) experiments were performed to calculate the heat involved in curing process and to calculate degree of cure [15, 16]. Fig. 1 shows the degree of cure and cure time graph for vinyl-ester resin at different temperatures.

It is clear from figure that degree of cure is the function of both temperature and time, it increases as temperature or time of curing increases. However, the rate of cure decrease as the degree of cure reaches maximum value for a particular temperature. At low cure temperature, degree of cure is low in comparison to it at higher cure temperature. As cure temperature increases, the rate of cure also increases and leads to high degree of cure even at low time [17, 18].

Fig. 2 shows the viscosity variation of epoxy resin during isothermal curing. The initial viscosity of resin is very low. However, it is increased as the cycle time increases at a particular temperature, the time to increase the viscosity decreased as the cure temperature is increased [19, 20]. At early stage of curing the rate of increase of viscosity was low up to gel time, after gel time viscosity increased rapidly and resin was converted into matrix or solid mass.

In composite processing generally in liquid composite molding, proper flow of resin is required to produce void free parts. The viscosity of thermoset resins increases rapidly as curing reaction is initiated, and the simultaneous flow of resin with curing reaction may lead to voids and poor interlaminar adhesion. Permeability through fibre network is essential parameter which basically govern the resin flow through fibre network. Gebart [21] proposed permeability equations for unidirectional fibre network as following.

$$\text{In the fibre direction : } P_{11} = \frac{2d_f^2}{C_1} \frac{1 - V_f^3}{V_f^2} \quad (1)$$

$$\text{Normal to fibre direction : } P_{22} = C_2 \left(\sqrt{\frac{V_{fmax}}{V_f}} \right) \quad (2)$$

Fig. 2 Variation of viscosity during isothermal curing of epoxy. Reproduced from Kamal, M.R., 1974. Thermoset characterization for moldability analysis. *Polymer Engineering & Science* 14 (3), 231–239.

Where, d_f is the fibre diameter, V_f is the fibre volume fraction, C_1 is the hydraulic radius between the fibres and C_2 is a constant.

Hubert and Pourstrip [22] further investigated that good resin flow through fibre perform is not sufficient to produce consolidated part. Compaction pressure is also required to squeeze out air bubbles and to produce void-free parts.

Processing of Polymers and its Composites

There are numerous processing techniques which are available to manufacture the polymer and their composites. These techniques are developed in such a way that it would be able to produce part of different design parameters, different material properties as well as to minimize the defects while manufacturing. The use of fundamental science in the processing techniques have developed many new techniques as well as improved the existing techniques significantly [23]. Several researchers have worked on the use and optimization of the following processing techniques for different applications.

Injection Molding

Injection molding is a technique to transfer polymer materials into useful products of various shapes. It is a cost-effective method, and can produce complex shape parts not only with a high precision but also at a high production rate. Fig. 3 shows the schematic diagram of injection molding process which comprises a hydraulic unit, injection unit and clamping unit.

High production rate of injection molding process is closely associated with injection velocity. Yang and Gao [24] used an adaptive controller to control the injection velocity. The pole-placement technique was found to be suitable for different molding conditions. Shrinkage is the problem that is associated with injection molding process. If a hollow or a partially hollow part is to be produced by using injection molding technique then water assisted or gas assisted injection molding can overcome the problem of shrinkage. Although, process cycle for gas and water assisted injection molding is almost same, water assisted injection molding have several advantages over gas assisted injection molding. The cooling cycle of water assisted injection molding technique is less than gas assisted injection technology because of high thermal conductivity of water. Compaction of water is higher than that of gas because water is incompressible in nature. Water injection technology (WIT) can produce part with high internal surface than gas assisted injection molding. When the water is injected into the melt, its viscous front acts as a ram and this viscous front forces the molten material forward, and eventually helps to reduce defects in the final part [25].

Water assisted injection molding technology is of two types, partially filled (short-shot molding) and fully filled (full-shot molding) mold with polymer melt. After filling the polymer melt into the mold, water is injected into the core of polymer melt. The schematic diagram of water assisted injection molding is shown in Fig. 4.

Liu and Chen [26] used Taguchi method to optimize the process parameters of water assisted injection molding for thermoplastic composites. Optimization of parameters was done on the basis of length of water penetration into the core. In conventional injection molding process polymer melt starts to cool very rapidly as it enters the mold cavity and the molded part then undergoes a shrinkage. In water assisted injection molding water penetrates into the core of polymeric melt and pushes it against the mold wall which helps to minimize the shrinkage. Short-shot size were found to be significant parameter which affect the length of penetration. Liu and Chen [27] investigated the design of water injection pins. As the polymer melt is forced into the mold cavity, melt could stick to the small opening of water injection pins. Two type of rings were selected to study this behaviour. Result showed that ring type water pins have very less chance of sticking by polymer melt. However, due to limited volumetric flow rate the possibility of incomplete filling is severe. On the other hand the possibility of sticking of orifice type pins is very high. However, its larger hole diameter leads to complete filling of mold.

Thin wall injection molding has many applications in electronic industry especially in micro-electro-mechanical systems. However, injection molding process for manufacturing parts with very low thickness is difficult and complicated. Song *et al.* [28] used Taguchi method to investigate the different process parameters as shown in Table 2. Table 3 shows the results of the filling area with respect to different parameters of injection molding process.

The result shows that by increasing injection rate the filling ratio increases. Higher melt temperature and injection pressure is also required in molding process to attain maximum filling of mold as shown in Figs. 5 and 6.

Filling volume was calculated by varying injection rate up to five values. The effect of melt temperature and injection pressure on filling volume was also investigated by varying melt temperature gradually from 190°C to 250°C and injection pressure from 50 MPa to 110 MPa as shown in Fig. 6. Ramakrishnan and Mao [29] studied the effect of injection molding process on the shrinkage of a polymer gear part. Taguchi orthogonal array design and ANOVA method was used to optimize the process parameters which were identified the most significant for volumetric shrinkage. Melt temperature was found to be most significant contributor for volumetric shrinkage followed by the pressure. Huang and Deng [30] investigated the effect of short-shot size, water pressure, melt temperature and water injection delay time on water penetration length. The orthogonal array of Taguchi method was used to find the optimal parameters resulting in maximum penetration length. Different levels of $L_9(3^4)$ orthogonal array were chosen as per Table 4.

Short-shot size was found to be most significant parameter. However, short-shot size (68.5%), melt temperature of 220°C , water pressure of 9 MPa and water injection delay time of 5 s were the optimal parameters to maximize the water penetration length. The crystallinity of final product was also analysed by using differential scanning calorimetry (DSC) at the beginning and the end of the channel of curved pipe. Samples for DSC were taken from inner, middle and outer layer, maximum crystallinity was observed at the middle layer sample took from the beginning of curved pipe.

Pultrusion Process

The term pultrusion is the combination of two words “pull” and “extrusion”. It is the process in which fibres are pulled into resin and then allowed to pass through heated die. Pultrusion is a molding process for producing structural members of uniform cross-sectional area. Solid and hollow structures can be processed easily by the pultrusion process [31]. Advancement in manufacturing processes have made it compatible for the manufacturing of channels, beams, bars and many other profiles. Fig. 7 shows a schematic diagram of pultrusion line for producing polymer composites. Fibres from roving creels and mat creels are pulled into resin bath through a guide. After the impregnation of fibres into resin, the impregnated fibres are pulled into performer and then into a long die. Performer helps to squeeze out excess resin whereas curing and compaction is done in the die. At the end of the pultrusion line, pull blocks pull the cured parts from the die and it is cut from continues pultrusion line as per required length [32].

Pultrusion have several advantages over other composite processing techniques as it could allow to produce any transportable length [33]. Moreover, the cost of product is very less in comparison to other processing techniques. Its cost is approximately 41% of the filament winding technique and 26% of the hand layup technique [34]. However, the part with non-uniform cross-section area and complex shapes cannot be produced by using the pultrusion technique. Moreover, poor dimensional accuracy and non-uniform curing problems are also associated with pultrusion technique [31].

Fig. 7 Schematic of a pultrusion process. Reproduced from Mallick, P.K., 2007. *Fiber-Reinforced Composites: Materials, Manufacturing, and Design*. CRC Press.

Fig. 8 Viscosity and temperature variations of a thermosetting resin in a pultrusion die. Reproduced from Mallick, P.K., 2007. *Fiber-Reinforced Composites: Materials, Manufacturing, and Design*. CRC Press.

In thermosetting pultrusion the mechanical properties of final product depends upon the degree of cure and its uniformity. Non-uniform curing of component during pultrusion leads to an inhomogeneous structure. There are number of parameters those effect the final properties of pultruded parts. Fibre wet-out, die temperature, die length, pulling speed and properties of fibre are the main process parameters required to control in order to produce final product with high quality. Fibre wet-out take place through capillary action and low resin viscosity as well as slow line speed increases the capillary action [35]. The die length, temperature and pulling speed are found to be responsible for the degree of cure of pultruded member, and are controlled to attain maximum degree of cure. Fig. 8 shows that resin viscosity decreased at the entrance of die and this aids to proper wet-out fibres. However, as the exothermic curing take place, resin viscosity and temperature of fibre-resin stream increases rapidly. Due to the effect of curing reaction the temperature of fibre-resin stream increases more than the temperature of die. The locations of this peak temperature is defined by the pulling speed of resin-fibre stream through die as shown in Fig. 9.

High pulling speed shifts the peak temperature location toward the end of the die which further increase the pulling force. Although, production rate is increased as pulling speed increases, low degree of cure and poor surface quality would appear. Bibbo [36] developed a theoretical model to calculate the factors which affects the pulling force.

In thermoplastic pultrusion there is no curing reaction of polymer like as in thermoset. Pre-impregnated tapes or prepregs are consolidated and shaped in the die as shown in Fig. 10.

In the die assembly, the control panel is employed to cool the part at controlled rate. Because there is need to control the cooling rate of polymer in die in order to obtain the crystalline part and to achieve the best mechanical properties [37]. Dharia and Schott [35] conducted the study to determine the effect of pull speed and resin viscosity on fibre wet-out. It was noted that the penetration of resin into the fibre yarn or bundle decreases while the coat of roving form outsides increases with increase in pull speed and resin viscosity. It is due to the fact that the penetration at low speed is controlled by capillary forces whereas at high

Fig. 10 Thermoplastic pultrusion process. Reproduced from Van de Velde, K., Kiekens, P., 2001. Thermoplastic pultrusion of natural fibre reinforced composites. *Composite structures* 54 (2–3), 355–360.

speed squeeze force is responsible for the same. Chen and Wang [38] investigated the effect of die temperature, pulling rate and fibre content on mechanical properties of glass reinforced polystyrene polymer matrix composite. The mechanical properties improved with increasing the fibre content and die temperature, whereas pulling speed had an inverse effect on mechanical properties of glass/polystyrene composites. Carlsson and Astrom [39] also investigated the effect of pultrusion parameters on properties of glass fibre reinforced polypropylene thermoplastic composites. The process variables such as preheater temperature, cooled die temperature, heated die temperature and pulling speed were varied by using Taguchi method to obtain optimum value of mechanical properties, surface finish, pulling force and fibre distribution over a cross-section.

Fig. 11 (a) and **(b)** shows that fibre distribution is enhanced with decrease in pulling speed and increase in heated die temperature. Flexural strength also improved with increase in heated die temperature. However, preheater temperature put inverse effect on the flexural modulus. Gloss increases with increase in pulling speed, and decrease with increase in preheater temperature as shown in **Fig. 12 (a)** and **(b)**.

Roughness increases with increase in preheater temperature whereas, it decreases with increase in pulling speed as shown in **Fig. 13 (a)** and **(b)**. However, increment in pulling also increases the pulling force which is required to pull the pultruded parts and it leads to the requirement of high power input for the pultrusion process.

Li *et al.* [40] investigated the formation of blister and also investigated the process variables those were responsible for it. The result showed that low temperature of resin and higher pulling speed is responsible for the formation of blister whereas longer dies could help to prevent blister formation.

Filament Winding

Filament winding is a process in which a yarn of resin impregnated fibres is wrapped around a rotating mandrel and then this wrapped mandrel is cured. Applications of filament winding is to produce axisymmetric hollow composites as tanks, pipelines and pressure vessels. **Fig. 14** shows the schematic diagram of filament winding process.

Fig. 11 Fibre distribution versus (a) pulling speed, and (b) heated die temperature. 5 is assigned to well distribute fibres. Reproduced from Carlsson, A., Åström, B.T., 1998. Fig. 12 Gloss versus (a) preheater temperature, and (b) pulling speed. 5 denotes a shiny surface whereas, 1 corresponds to a matt surface. Reproduced from Carlsson, A., Åström, B.T., 1998. Experimental investigation of pultrusion of glass fibre reinforced polypropylene composites. Composites Part A: Applied Science and Manufacturing 29 (5–6), 585–593.

Fibres from a series of creels are pulled into a resin bath for the impregnation. Before to wrap around the rotating mandrel, fibres are gathered into a yarn. The carriage guides the band or yarn while it is going to be wrapped on the mandrel. Wind angle, that is the angle of wrapped yarn with respect to mandrel axis, is generated by the simultaneous control of traverse speed of carriage and rotating speed of mandrel. The gear box is used to control the speed relation between carriage feed and rotational speed of mandrel. Eq. [3] is used to calculate the wind angle.

$$\theta = \frac{2\pi Nr}{v} \quad (3)$$

Where, N is the rotational speed of mandrel per minute, r is the radius of mandrel and v is the carriage feed.

The carriage transverse speed and mandrel rotating speed can also be controlled effectively by using numerical controls in filament winding machines [41]. CNC can be used for filament winding process to produce complex shapes along with high production rate. The required thickness of part could be generated by winding the number of layers over the mandrel. After the winding process the heat is given to mandrel for the completion of curing for thermoset matrix and then the cured part is extracted from mandrel. Resin viscosity, other properties and its processing time is responsible for the voids and delamination defects in the parts produced by filament winding process. The range of viscosity is preferred “between” 1000–2000 cP such that proper wet-out of moving strands could take place. Moreover, the pot life of resin should be higher so that filament winding could be done before

the gelation starts. With the limited pot life of resin, the large parts could take more winding time between two consecutive layers which can result in delamination of final cured part.

High fracture toughness, reparability and weldability are the advantages of thermoplastics over thermoset materials. Owing to these advantages the interest in filament winding of thermoplastics is increasing day by day [42, 43]. Fig. 15 shows the schematic diagram of filament winding process for thermoplastic material.

Fibres are impregnated with the matrix or resin in order to produce part through filament winding [44]. However, the thermoplastic materials do not have curing cycle like as thermosets, only consolidation of thermoplastic is required. Pre-impregnated fibres or tape can be used in this process which have to go through different heating units so that proper consolidation can take place. Moreover, in case of thermoplastic materials the in-situ consolidation that is one step consolidation during winding is possible.

Different to thermoset filament winding process, thermoplastic materials is melted before the impregnation process so that impregnation and consolidation can take place properly. Temperature controls the viscosity of thermoplastic polymer, which is the responsible parameter for the impregnation and consolidation. Along with temperature, the process velocity and consolidation pressure are the important parameters of the filament winding process for thermoplastic materials. Mechanical performance of final part also depends on the winding patterns and crossing points in cross winding [45, 46].

Impregnation of fibres in thermoplastic material is highly time sensitive because of its high viscosity. Thermoplastic materials needs to be heated up more than the melting temperature so that proper impregnation and consolidation can take place. The heat source is the integral part of filament winding process for thermoplastic materials [47]. Schledjewski and Miaris [48] investigated

the parameters to select the heat source for in-situ consolidation of thermoplastic matrix. Beyler *et al.* [49] and Roselli *et al.* [50] have measured the use of laser as heat source for consolidation of thermoplastic tape. However, the effect of hot gas torch [51] and infrared radiation [52] has also been investigated on consolidation as heating methods.

For the consolidation of part, the consolidation roller applies the pressure at the nip point and the temperature of roller is controlled within the range of 60–90°C [53]. Khan *et al.* [54] have also worked to improve the quality and mechanical performance of wound product, and found that adjustable mandrel temperature can help to reduce temperature gradient which leads to improve the quality of final product. Kugler and Moon [55] revealed that by lowering the cooling rate the quality of wound product can be improved further. Lauke and Friedrich [42] investigated the processing parameters of filament winding for manufacturing thermoplastic composites. Consolidation force was calculated by varying nip point temperature, winding speed and IR-heating power. It is clear from Fig. 16 that maximum force was obtained at the highest temperature of hot air and it results in the best consolidation.

At high value of heating power, higher compaction power could be obtained at velocity 10 mm/s and 25 mm/s but not at 50 mm/s. However, at low value of heating power, maximum compaction is quite low even at low winding speed as shown in Fig. 17. The effect of heating power on maximum force can also be estimated from Fig. 18 at mandrel temperature of 100°C.

Compaction force increase up to a particular value of heating power and after then it becomes more or less constant. Because the temperature of impregnated resin, at the end of the preheater, increases with increase in heating power up to its melting temperature after that temperature of resin becomes constant. Similarly, at low heating power the melting temperature could not be obtained and thus, consolidation force decreases. Mertiny and Ellyin [56] studied the influence of filament winding tension on properties of glass-fibre reinforced composite. Mechanical testing was done on the specimens which were manufactured under different winding tension. Results showed that fibre compaction increases with increase in tow tension during filament winding.

Fig. 17 Maximum axial force versus winding speed at mandrel and hot air temperature 100 and 360°C respectively. Reproduced from Lauke, B., Friedrich, K., 1993. Evaluation of processing parameters of thermoplastic composites fabricated by filament winding. *Composites Manufacturing* 4 (2), 93–101.

Fig. 18 Maximum axial force versus IR power. Reproduced from Lauke, B., Friedrich, K., 1993. Evaluation of processing parameters of thermoplastic composites fabricated by filament winding. *Composites Manufacturing* 4 (2), 93–101.

Fibre volume fraction was also improved by the high value of tow tension. Mechanical properties of specimens those were manufactured with low and high tow tension, indicated that specimens with tow tension suitable for the fibre dominated applications whereas high tow tension specimens exhibited decrease in the failure strength at matrix dominated applications.

Compression Molding Process

The compression molding technique can produce parts with complex geometry in short time period. Thus, it is suitable for mass production of parts. It is one of the easiest method to produce composite materials as it can transform sheets into final product of the shape of die or mold. This process is used mostly because the scrap is minimum, whereas surface imperfection and waviness defects are still associated with this process. This technique requires the simultaneous control of processing parameters that is pressure, temperature and time. Pressure is required to flow the resin and to remove air bubbles from mold. Whereas, temperature is useful to originate or accelerate the curing reaction. Mallick and Raghupathi [57] discussed the complex heat transfer phenomenon of compression molding process. Fig. 19 shows that surface layer of prepreg approaches the mold temperature and then it is almost same with mold temperature.

Due to low thermal conductivity of fibre, the centreline temperature increases gradually until curing reaction take place at the mid of the prepreg. Owing to the low thermal conductivity of fibres, the heat generated by exothermic curing reaction at the mid of prepreg is not transferred to the top of the surface and eventually centreline temperature increases swiftly to the peak value. Curing of prepreg in compression molding begins at surface and moves inward. However, heat generated by exothermic reaction increase the temperature of the middle of the part and this high temperature may result in the chemical degradation of the resin, hence, high temperature of mold should be avoided.

Among all the defects, blisters are the most commonly occurring defects in compression molding. These are the interlaminar cracks formed due to internal gas pressure as the result of entrapped air between two consecutive layers. Griffith and Shanask [58]

Fig. 19 Representation of temperature-time curves during molding. Mallick, P., Raghupathi, N., 1979. Effect of cure cycle on mechanical properties of thick section fiber-reinforced poly/thermoset moldings. *Polymer Engineering & Science* 19 (11), 774–778.

suggested vacuum molding method to minimize the entrapped air from the mold. Khondker *et al.* [59] used a novel processing technique for manufacturing of jute yarn reinforced thermoplastic matrix composites. Polymer material was braided around the jute yarn to manufacture an intermediate material called microbraid yarn. These microbraid yarns were then wrapped around the metallic plate and this metallic frame was put into compression mold to fabricate unidirectional composites. Mechanical properties of manufactured composites were evaluated. Fibre/Matrix interaction was increased due to improvements in wettability and proper matrix fusion, this interfacial interaction leads to effective stress transfer between fibre and matrix. Hence, the improvement in mechanical properties of microbraid composites can be associated to improvement in wettability of resin into fibre, and interfacial adhesion. Hernandez *et al.* [60] studied the effect of curing cycle on interlaminar shear strength of polymer matrix composites. X-ray micro-tomography was used to determine the effect of curing cycle on void volume and shape. Rheological and thermo-chemical experiments helps to define temperature range for compression molding technique. Specimens were manufactured at different temperatures and 2 bar of pressure. It was found that by increasing the dwell time before gelation helps to reduce void fraction in laminates. Interlaminar shear stress test was conducted for different samples and result show that it decreases with increase in void content. Chani *et al.* [61] analysed the effect of time, temperature and pressure on output. Taguchi method was used to investigate the optimum parameter setting of the compression molding machine. Different levels of parameters considered for the design of experiment are shown in Table 5.

The output responses *i.e.*, tensile and compressive strength for each experimental set are shown in Table 6. It is seen from the table that the tensile and compressive strength are significantly influenced by temperature, pressure and hold duration. The S/N ratio plots shown in Fig. 20 demonstrate the effect of pressure, temperature, and hold duration on the combined response *i.e.*, tensile and compressive strength. The best properties were achieved at pressure of 140 MPa, temperature of 150°C, and hold duration of 30 min.

Resin Transfer Molding (RTM)

In the resin transfer molding process the thermoset resin is injected into a closed mold, where it wet-out the fibres and fills the empty space between fibres. The resin is injected at the lowest point of mold cavity under pressure. Curing of resin is done in mold either at room temperature or at temperature more than room temperature depending upon the type of resin is used. After the curing of part, the mold is dismantled and part is prepared for further secondary operations. RTM is a low pressure process and in comparison to compression molding process it has low tooling cost. It is a cost-effective and labour intensive process, suitable for low to mid volume rate of production.

Thermoset materials are the best choice for the resin transfer molding processes because of low viscosity. Due to low viscosity of thermoset resin, the resistance offered by fibrous perform in the flow of resin is minimum. Hence, the empty space at micron level between the fibres can be filled easily. The viscosity of thermosets lies between 0.1 and 0.5 Pa S, whereas, the same for thermoplastic material varies between 10.2 and 10.6 Pa S. Owing to high viscosity of thermoplastic materials it requires high injection pressure which results into high cost of equipment to be used for RTM processes. Moreover, high injection pressure could displace the fibres and could create resin rich areas which may alter the mechanical properties of final product. Permeability is the important parameter to be considered in RTM process. Although, mechanical properties increases as fibre volume increases, the flow of resin through fibres or the permeability of fibre perform decreases [62, 63]. The modifications in RTM process has been proposed to eliminate the problems of fibre volume fraction and large dimension of the components along with reduction in mold filling time. Chang *et al.* [23] combined the RTM process with compression molding to fabricate fibre reinforced plastic as shown in Fig. 21.

Process variables for this modification were optimized by using Taguchi method to obtain best quality of CRTM products. Compression pressure and resin temperature found to be significant factors for improving the mechanical properties of the part. Whereas, the effect of pre-heated mold temperature was negligible. Low compression pressure and viscosity could help to obtain the part with high quality. Low compression pressure is required in CRTM technology because low compression pressure take more time to be applied, which results in better wetting of fibre perform. Low cycle time, low capital investment and good surface

Table 5 Factors and levels considered in compression molding process

Factor	Levels			
	0	1	2	3
A – Pressure (kN)	100	120	140	160
B – Temperature (°C)	90	120	150	180
C – Hold time (min)	10	20	30	40

Note: Sreekumar, P., *et al.*, 2007. A comparative study on mechanical properties of sisal-leaf fibre-reinforced polyester composites prepared by resin transfer and compression moulding techniques. *Composites Science and Technology* 67 (3–4), 453–461.

quality part produced by RTM process has made it attractive for manufacturing of automobile components. Sreekumar *et al.* [64] compared the mechanical and physical properties of sisal-leaf fibre reinforced polyester fabricated by compression molding and RTM. **Table 7** shows the void content of parts manufactured by RTM and compression molding at different fibre volume fraction.

Void content increases with increase in fibre volume fraction and it was found to be more in the parts of compression molding technique. Water absorption in a fibrous composite is also due to micro cracks, voids and due to hydrophilic nature of polyester. **Fig. 22** shows mole percentage of water uptake at equilibrium (Q_e) with respect to fibre content.

Neat polymer resin exhibit very low water absorption due to cross linked structure. However, as the fibre volume fraction is increased the water uptake also increases. Along with other factors, tubular structure of fibre increases the water penetration owing to capillary action. Water absorption of composite prepared with RTM technique was also less than that of in compression molding because of good fibre/matrix interaction in RTM. Indira *et al.* [65] also compared the RTM and compression molding techniques for manufacturing the banana-fibre reinforced phenol formaldehyde composites, and results exhibited the same trend in terms of mechanical properties as obtained by Sreekumar *et al.* [64] for two different techniques which were used for manufacturing composites. Papargyris *et al.* [66] used two different heating methods in RTM for processing carbon fibre epoxy composites. Mechanical and physical properties were compared with respect to these methods. It was found that microwave heating process reduces cure cycle, energy requirement and operational cost. In comparison to conventional heating method, microwave heating reduces 50% cure cycle and shows 9% increase in the interlaminar shear strength. Whereas, flexural properties found to be same for normalized common fibre volume fraction.

Careful examination of SEM photographs in **Fig. 23** revealed the poor interfacial bonding and more fibre pull out of parts produced by conventional method than parts produced by microwave heating. **Fig. 24(a)** and **(b)** shows clean fibres in conventionally cured (thermally cured) and fibre coated with significant amount of resin thoroughly for microwave cured parts respectively.

Lee *et al.* [67] measured the effects of glass fibre surface modification on the properties of composite and on the flow characteristics of unsaturated polyester in resin transfer molding process. Glass fibre surface was modified by using γ - MPS treatment, and it was found that permeability of fibre perform decreased because of capillary pressure effect. However, void content in composites with γ - MPS treated glass perform was lower than that of untreated fabric perform, and flexural properties

of treated glass reinforced composites also improved. High surface quality is required for the part to be used in automotive applications and it is difficult to achieve for RTM technique due to different process and material related issues. Shrinkage during curing of polyester resins make it difficult to obtain high surface finish and part with tight tolerance. Haider *et al.* [68] and Palardy *et al.* [69] used low profile additives (LPA) to reduce cure shrinkage. Taguchi method was used to investigate the effect parameters on the process cycle time and pressure variation, ultimately on surface finish of parts produced by RTM method. Pressure sensors were inserted at various locations of mold cavity to observe pressure during different stages of curing. The minimum cure shrinkage was observed at critical amount of LPA that is at 10%. Due to expansion of LPA, the pressure increases significantly at the later stages of curing. The significant effect of increase in pressure was observed on surface roughness as the surface finish increased with increase in pressure. Injection time and cure gradient found to be decreased with increase in injection pressure. Void is another critical defect which not only effects the surface finish but also uneven void distribution may result in uneven stress distribution. Leclerc and Ruiz [70] conducted the experimental analysis on different fibrous reinforcements to measure the effect of injection parameters of RTM manufacturing on part quality and mechanical performance or ultimately on the macro and micro voids. Based on void measurement and mechanical testing of parts, the relation between void content and their impact on mechanical properties was made and it leads to an optimal value of impregnation velocity. Kaynak *et al.* [71] investigated the

experimental analysis to measure the effect of RTM mold temperature, vacuum and initial resin temperature on the mechanical properties of woven glass epoxy composite. Characterisation of samples was done by ultrasonic C-Scan inspection, thermal analysis, mechanical testing and scanning electron microscopy. Highest mechanical properties were obtained at 60°C temperature of mold with the application of vacuum, and at 28°C initial temperature of resin. Under the application of vacuum the mechanical properties were improved due to decrease in void content in composites. Moreover, mechanical properties are also improved when initial temperature was increased from 15°C to 25°C. Rassmann *et al.* [72] studied the effect of processing conditions of resin transfer molding on mechanical and absorption properties of natural kenaf fibre polyester laminates. At low fibre volume fraction, the tensile and flexural properties increased with increase in mold pressure following injection. However, mold temperature found to be insignificant with respect to impact on mechanical properties.

Bag Molding Process

Bag molding process is used to manufacture polymer based composite materials. The raw material for bag molding process is an uncured prepreg. To convert this raw material into final product the prepreg is heated in an autoclave. Under the effect of temperature, the resin viscosity of partially cured prepreg first decrease up to gel point and then chemical reaction begins and convert the uncured part into final useful product. Fig. 25 shows the typical cure cycle for carbon epoxy prepreg or composite.

After the gel time, the flow of resin from the prepreps decrease significantly. For the proper flow, dwell at temperature lower than the gel time is necessary because it helps to attain uniform temperature throughout and, it gives time to flow resin from prepreg at low viscosity [73]. Fig. 26 shows the effect of dwell time on gelation.

Fig. 26 Effect of dwelling on gel time. Reproduced from Purslow, D., Childs, R., 1986. Autoclave molding of carbon fibre-reinforced epoxies. *Composites* 17 (2), 127–136.

Fig. 27 VARTM process. Reproduced from Kedari, V.R., Farah, B.I., Hsiao, K.-T., 2011. Effects of vacuum pressure, inlet pressure, and mold temperature on the void content, volume fraction of polyester/e-glass fiber composites manufactured with VARTM process. *Journal of composite materials* 45 (26), 2727–2742.

Loss and Springer [74] investigated the thermomechanical behaviour of polymer or resin in a vacuum bag molding process. Experimental study found that cure pressure must be applied just before the gel time so that excess resin could be squeezed out and uniform wetting of prepreg could take place. The cure time required with respect to different cure temperature was also calculated for a particular value of degree of cure in graphite fibre epoxy laminates.

Vacuum-assisted resin transfer molding (VARTM)

Fig. 27 shows a schematic diagram of VARTM process, in which single sided mold is used and sealed with bag for creating vacuum inside a bag. Vacuum not only assists to remove air from mold but also compact the fibres. The resin is drawn into the mold under atmospheric pressure. As the resin infusion take place at atmospheric pressure, the time to fill the mold is very slow in comparison to RTM process [75].

VARTM process is able to manufacture large and complex shapes with high quality. Moreover, it is simple process and can be easily modified for processing different part geometries. All these benefits have made it suitable for marine, aerospace, infrastructure building and defence applications. However, VARTM is not robust as the RTM or autoclave processes. Because compaction pressure on perform or fibres is limited, which eventually leads to low fibre volume fraction in final part.

Gutowski *et al.* [76] established the relation between compaction pressure (P_{comp}) and fibre volume fraction (V_F), which is given as Eq. [4]

$$P_{comp} = A \frac{((V_F/V_{F0}) - 1)}{((1/V_F) - (1/V_{F\infty}))^4} \quad (4)$$

Where, A is the perform spring constant, V_{F0} is the fibre volume fraction at zero compaction pressure and $V_{F\infty}$ is the ultimate fibre volume fraction at infinite compaction pressure. Robitaille and Gauvin [77] introduced another empirical model as Eq. [5]

$$V_F = V_{F1} P_{comp}^B \quad (5)$$

Where, B is the stiffness exponent of fibre perform and V_{F1} is the fibre volume fraction at the unit reference compaction pressure. This model requires only two constants and compaction experiments could help for curve fitting. The thickness (h_2) of composite perform can also be calculated by using fibre volume fraction as per Eq. [6] [78].

$$h_2 = \frac{n_p w_A}{\rho_F V_F} \quad (6)$$

Where, n_p = Number of plies of mats
 w_A = weight per unit area of fibre mat
 ρ_F = Density of fibre material

Permeability is another important factor which affects the resin flow through fibre perform. Kozeny-Carman equation which established relation between permeability (K) and fibre volume fraction is [79] defined as per Eq. [7].

$$K = k \frac{(1 - V_F)^3}{V_F^2} \quad (7)$$

Where, k is a constant, determined from experiments.

Li *et al.* [78] studied relaxation process to reduce compaction variation of fibre perform. In relaxation process enough time is given to mold by closing all gates to distribute compaction uniformly inside the vacuum bag. Compaction relaxation process affects the curing reaction and resin viscosity. More time between the resin filling and curing reaction will allow a complete relaxation process and a more uniform final part. More and more vents could help to accelerate the compaction process [80]. Goren and Atas [81] used PLC as a control unit to control the curing cycle. The vacuum and temperature was controlled by automatic control unit in order to produce void free product with high quality. The advantage of PLC as a control unit is its flexibility to change cure conditions. Void content and fibre volume fraction of a part manufactured by using VARTM process has significant effect on the quality and mechanical properties. Kedari *et al.* [75] investigated the effects of VARTM parameters such as mold temperature, vacuum pressure and inlet pressure on volume fraction and void fraction of glass fibre reinforced polyester composites. Experimental results suggested that fibre volume fraction increases with increase in mold temperature and vent vacuum pressure, due to decrease in resin viscosity. However, void content could increase at higher temperature of mold if injection pressure is not varied accordingly. Although, surface energy of fibres is required more than that of resin, surface energy and viscosity of resin decreases due to increase in temperature of mold or resin [15] which leads to decrease in rise of capillary height of resin, and results in poor wet-out of fibres. However, higher surface energy of fibres leads to strong interfacial bond or more adhesion forces between fibre and matrix. It was concluded that high vacuum, high mold temperature and low inlet pressure can produce a part with low void content and high fibre volume fraction through VARTM process.

The pressure gradient developed during the infusion in VARTM technique and it is responsible for the resin flow into the mold. The resin flow does not stop even after the closer of inlet. This post-filling behaviour disturb the fibre volume fraction and final thickness of cured composite. Simacek *et al.* [80, 82] examined the impact of post-filling flow on fibre volume fraction and thickness of final part. Membrane based VARTM process was used to determine the thickness development during post-infusion. Membrane on the mold acts as a continuous vent during the infusion process and helps to obtain uniform thickness.

Autoclave Process

Autoclave processing is one of the best method for processing laminates with large complexity. By using this technique fibre reinforced plastic composites can be produced for high-performance applications. Autoclave processing technique is very similar to bag molding technique with some modifications [83]. In this technique prepreg are cut into the shape of part to be produced and, then stacked. Then the stacking of prepreps is covered with bleeder and breather in a vacuum bag as shown in Fig. 28.

After filling the resin into the mold the whole assembly is placed into the autoclave where, the pressure and temperature is given to assembly at controlled rate as per curing cycle. At the end of the cycle the cured part is demolded and prepared for further operations. The pressure inside the autoclave is applied to the laminate to consolidate the laminate. The purpose is not only to obtain desired fibre volume fraction but also to remove void formation during cuing cycle.

It is difficult to measure the robustness of autoclave process because a number of parameters are involved in processing. Intelligent process control have been used to minimize the process variations [84–86]. Thermocouples or dielectric sensors has been used to measure autoclave parameters in order to minimize process cycle time as well as temperature gradient of a part during curing [87–90]. Kaushik and Raghavan [91] studied parameters which affect the process-induced warp and reduce the dimensional accuracy of part prepared from thermoset polymer composite during autoclave processing. Static and dynamic

frictional coefficients were measured with respect to process time, degree of cure and ramp rate to quantify the tool-part interaction which leads to warpage of composite part. Experimental result shows that both frictional coefficients were maximum at start of cure cycle and changed, as the degree of cure and ramp rate change, due to change in the tool-part interaction. Abraham *et al.* [92] made comparison of properties of glass fibre reinforced epoxy composites manufactured by resin transfer molding and wet-layup with autoclave consolidation. Table 8 summarises the various characteristics of both techniques.

Curing cycle for both the techniques is also different as the number of parameters are different. Figs. 29 and 30 shows the curing cycle for RTM and autoclave processes respectively.

In step 1 resin degasses mold under vacuum at 30°C and in step 2 resin is injected into the mold of temperature 75°C at pressure less than atmospheric as shown in Fig. 29. After injection, temperature is raised to 100°C and pressure to atmospheric in step 3. In step 4 composite is cured for 1 hour at identical parameters. 5 and 6 are the post curing parameters of the process.

In step 1 temperature is raised to 50°C and in 2 it dwells for 60 minutes as shown in Fig. 30. After this temperature is raised to 100°C in step 3 and it dwells again in step 4. In step 5 temperature is ramped to 40°C and in step 6 composite is demoulded and post cured.

Results showed that a higher volume fraction could be obtained by using autoclave technology, which leads to higher fibre dominated properties. However, normalized results on the basis of fibre volume fraction for both technique were similar. The matrix dominated properties that is interlaminar shear stress (ILSS) was found to be higher in RTM samples as shown in Table 9.

Manufacturing Processes Particularly for Thermoplastic Polymers

The processing techniques of thermoset materials could also be used for the manufacturing of thermoplastic materials and their composites. However, the thermal behaviour of these two types of polymers is different. The processing temperature for

thermoplastic materials is relatively higher than that of for thermosetting materials. Moreover, in thermoplastic materials no exothermic chemical reaction occurs during the processing. However, working temperature of thermoplastic material is higher than that for thermoset materials and, in the processing of thermoplastic materials and their composites high temperature and pressure is required to consolidate the final part. After consolidation the component is cooled at controlled rate so that residual stresses can be minimized and maximum crystallinity can be attained. Thermoplastic materials can be easily reshaped into useful product under the effect of pressure and temperature. Matched die forming, hydroforming and thermoforming are the basic techniques, which can be used to process thermoplastic materials [93].

Fig. 31 shows matched die forming technique which consists of two matching dies controlled by a hydraulic process. By using this technique a part with a uniform thickness can be formed under pressure. The limitation of producing part with non-uniform thickness can be resolved by using hydroforming. Part with non-uniform thickness can be easily formed by using hydroforming technique.

In hydroforming technique as shown in **Fig. 32**, hydraulically operated diaphragm is used to generate pressure for deforming. Elastomeric diaphragm is installed inside the upper part of mold or die and in the lower part of die, the sheet is to be deformed is placed. The applications of this technique are limited because of the limitations of the elastomeric diaphragm [94].

Thermoforming is another processing technique in which thermoplastic sheets are formed into useful products. **Fig. 33** shows the process diagram of thermoforming. In this technique, the heat is given to sheet in order to increase its temperature up to forming temperature which is slightly higher than the glass transition temperature of thermoplastic. Then preheated sheet is placed in the mold and, vacuum or pressure are applied to mold to form sheet into useful product.

Due to stretching, the polymer sheet undergoes the reduction in its thickness during the thermoforming operation. This reduction leads to a decline in the mechanical properties of formed part. Yang and Hung [95] used the Taguchi method and utility concept to obtain the optimum processing conditions of thermoforming process so that optimum thickness distribution of foam parts can be obtained. Heating temperature, vacuum pressure, plug material, plug speed and plug displacement process parameters were identified to be used in orthogonal array. Vacuum pressure and heating temperature were found to be the most significant factors. Increasing vacuum pressure and heating temperature results in the reduction of the thickness of foamed part.

Fig. 34 Schematic of diaphragm forming. Reproduced from Okine, R.K., 1989. Analysis of forming parts from advanced thermoplastic composite sheet materials. *Journal of Thermoplastic Composite Materials* 2 (1), 50–76.

However, thermoforming technique cannot be used to form reinforcing composites as the processing parameters are not suitable to produce it. If this forming technique is applied for thermoplastic matrix composites, it is not possible to stretch laminas without fibre breakage while forming take place. To overcome this problem, the prepreg is placed between deformable diaphragms and the edges of diaphragms are clamped into the die as shown in Fig. 34.

The process cycle for this modification is shown in Fig. 35. This cycle is for carbon fibre reinforced PEEK composite which is processed in autoclave [96].

The temperature of autoclave increased gradually above the melting temperature of PEEK then pressure is applied to consolidate the part. Cogswell [97] have defined the mechanism for the formation of thermoplastic matrix composites as shown in Fig. 36.

In the very first step of flow mechanism, molten polymer flows through the fibres under the effect of pressure called percolation and then fibres start to flow into transverse direction. Percolation and transverse flow of fibres helps to reduce voids, increase consolidation and increase interlaminar adhesion. Along with this intraply shearing and interply slip also take place.

Conclusion

The choice of more efficient processing technique to produce parts of polymer as well as its composite materials is important. There could be more than one method to produce a specific part but pros and cons of each process are always associated with it. The following are the conclusions that can be drawn from discussed manufacturing processes.

- (1) Although, degree of cure of thermoset polymer increases with increase in cure time and temperature. However, rate of cure decreases drastically as degree of cure approaches maximum value for a particular temperature. Viscosity of resin increases very rapidly after gel time of thermosets but gel time reduces drastically when curing is done at higher temperature. On the other hand, in case of thermoplastic polymers the material is deformed under the effect of pressure and temperature, after the consolidation deformed part is cooled at controlled rate. Whereas, in case of composites of thermoplastic materials the material is melted and after reinforcement it is consolidated at high pressure and then cooled at controlled rate.
- (2) Injection molding is the cost effective process which can produce parts of complex shapes at high production rate and with high level of precision. In injection molding process the injection velocity is significant parameter for filling the mold to produce parts with complicated geometry. Melt temperature is another prominent parameter to reduce volume shrinkage followed by its pressure. Whereas, short-shot size is the dominated factor in the calculation of water penetration length of water assisted injection molding process.

- (3) Pultrusion is another cost effective method as its cost is approximately 41% of filament winding technique and 26% of hand lay-up technique and it is suitable for producing parts of uniform cross-section area. Die length, temperature and pulling speed are the key parameters of pultrusion process for thermosets to attain maximum degree of cure.
- (4) Filament winding process is used to produce axisymmetric hollow parts. In filament winding process besides the viscosity of resin, high pot life of resin is preferred so that winding can take place before gelation starts. However, in case of thermoplastic the polymer is melted above melting temperature and consolidation force is required for the consolidation of part to make it useful.
- (5) Compression molding process is best for mass production and can produce parts with complex shapes at high production rate. Time, temperature and pressure are the three variables which decide the final properties of manufactured laminate.
- (6) RTM is a labour intensive and cost-effective method for the processing of polymer matrix composites. It is suitable for low to mid volume production rate. It is the best choice for the processing of thermoset matrix composites. Combination of this process with compression molding, known as hybrid technique of manufacturing can improve mechanical properties of final part significantly. However, comparison of RTM and compression molding has proved the RTM process to be best in terms of better physical and mechanical properties of final part.
- (7) In bag molding process the dwell at temperature lower than the gel time is the important step to minimize the defects in part or to maximize the quality of product. Vacuum bag process can be easily modified according to the shape of part to be produced and it is able to produce large and complex shapes of part with high quality. However, compaction pressure on fibre perform in this process is very low. So, this process is not as robust as RTM and autoclave processes. Moreover, mold filling time in this process is high which leads to less production rate in comparison to other processes.
- (8) Although, in comparison to RTM process the labour intensity in autoclave process is high with respect to the production output of both, most of the physical and mechanical properties of part produced by autoclave process are more than that of part of RTM process. Moreover, high fraction of fibre volume fraction can be achieved by autoclave process as compared to RTM process.

Nomenclature

AlN	Aluminum Nitride	HDPE	High Density Polyethylene
Al ₂ O ₃	Alumina	HNBR	Hydrogenated Nitrile Butadiene Rubber
BN	Boron Nitride	ILSS	Interlayer Shear Strength
CB	Carbon Black	MCF	Milled Carbon Fiber
CF	Carbon Fiber	MEMS	Microelectromechanical Systems
CFRP	Carbon Fiber Reinforced Polymer Composites	MWCO	Molecular Weight Cut-off
CNC	Cellulose Nanocrystal	PCB	Printed Circuit Board
CNT	Carbon Nanotubes	PCM	Structural Polymer Composite Materials
CNTB	Carbon Nanotube Bundle	PEI	Polyetherimide
CTE	Coefficient of Thermal Expansion	PEEK	Polyether Ether Ketone
DC	Direct Current	PMC	Polymer Matrix Composites
DGEBA	Diglycidyl Ether Bisphenol A	PMMA	Polymethyl Methacrylate
DMA	Dynamic Mechanical Analysis	PPS	Polyphenylene Sulfide
FA	Fly Ash	rGO	reduced Graphene Oxide
GNP	Graphene Nanoplatelet	SiC	Silicon Carbide
GNP	Graphene Nanoplatelets	TIM	Thermal Interface Materials
GO	Graphene Oxide	TPE	Carbon Thermoplastic Elastomeric

Introduction

During the last few decades, the use of polymer-based materials in a number of applications has increased very rapidly compared to synthetic materials (Pilla *et al.* 2009a,b; Zhang *et al.*, 2009). Polymers have simplified human lives and influenced every aspect of modern civilization. Today, different kinds of polymers are available from household to aerospace applications and can be easily seen in everyday life (Chalivendra *et al.*, 2003; Gao *et al.*, 2012). Different kinds of materials such as artificial fibers, elastomers, plastics, and polymer composites have been developed using polymers, and these materials are being tailored frequently to meet the desired industrial applications. Polymers have even replaced traditional metals and glass-based materials for a number of applications due to their ease of processing, low cost, and availability (Pinto *et al.*, 2014). However, due to rising environmental awareness, depletion of petroleum resources, and health concerns, the past few years have seen a dramatic shift in the development of novel materials derived from biorenewable resources. Polymer matrix composites (PMCs) are materials that use a polymer-based resin as a matrix material with some form of fibers embedded in the matrix, as reinforcement. Both thermosetting and thermoplastic polymers can be used for the matrix material. Common polymer composite thermosetting matrix materials include polyester, vinyl ester, epoxy, and thermoplastic matrix materials include polyether ether ketone (PEEK), polyetherimide (PEI), polyphenylene sulfide (PPS), polymethyl methacrylate (PMMA). The reinforcements used in such matrices are glass, carbon, and aramid fibers.

This article discusses various tailored behavior of polymer matrix composite materials in order to examine their mechanical, thermal, and electrical properties. The main purpose of this article is to study polymer composites that can meet the specific needs of various engineering applications.

Tailored Behavior Theory

Polymer matrix composite materials are not a new concept, but recent advances have brought many new and exciting composites into existence. By a smart choice of matrix and reinforcement (as well as the best manufacturing process to bring them together) it is possible to make significantly superior materials, with tailored properties for specific applications. In total, tailored behavior theory shows us how to achieve more valuable and practical results by changing some properties of polymer composites.

Thermoset or thermoplastic matrix resins reinforced by fibers are in polymer matrix composites that are much stiffer and stronger than the matrix. Polymer matrix composites are appealing because they are lighter, stronger, and stiffer than the unreinforced polymers or conventional metals, with the additional advantage that their properties and form can be tailored to find the best of a specific application. One of the most common uses of fiber reinforcements is in the military and aerospace industries; this includes carbon fibers and such organic fibers as aramids, liquid crystalline polymers, and ultrahigh-molecular-weight polyethylene. The properties of composite structures depend not only on the fiber reinforcements, but also on the polymer matrix, the characteristics of the interface between the fiber and matrix, and the manufacturing process used to form the finished structure (Park and Seo,

2011). Fiber reinforced polymer composites are also becoming agreeable in modern designs, because of their high specific strength, light weight and ability to be tailored for a specific usage. The development in the commercial and feasible applications of composite materials has motivated researchers to create the next generation of composites. New generation composites purpose to integrate more structural and nonstructural properties into the structure with the aim of enhancing the efficiency of the system as a whole. There have been many endeavors in improving or replacing structural fiber and matrix phases with active materials. Anyway, this methodology generally affects the structural properties of the composite and restricts their practical applications (Malakooti *et al.*, 2017). For example, lightness, durability, strength and ease of production mean that composites will play an increasing part in a boat construction. Despite all the new composites, fiber-reinforced polymer composites are here to stay for many years, though it will undoubtedly be in partnership with other exotic composites. Materials science and composite technology are developing rapidly, and new composites include carbon nanotube and epoxy mixtures. Newly, a small naval vessel with a hull built using carbon nanotubes was delivered as a concept project (Todd, 2020a,b,c). Fiber reinforced polymer composites are often used as structural components that display to extremely high or low heats. Examples such as carbon fiber reinforced polymer composites (CFRP) are lightweight, strong materials used in the manufacturing of innumerable products used in our daily consumption. It is a term used to describe a fiber-reinforced composite material that uses carbon fiber as the primary structural component (Todd, 2020a,b,c).

Dielectric polymer materials with a high dielectric constant and low dielectric loss find many industrial applications such as artificial muscles, energy storage, sensors, flexible electronics, and micro robotics, so it has attracted a lot of attention in the last years. One of the dielectric polymer non-functional cases is the low dielectric constant which was improved by tailoring dielectric properties of polymer composites resulting from controlling alignment of carbon nanotubes (Liu *et al.*, 2016). Also, graphene and its related combinations have been known as wonderful structural nano-fillers that can tailor the properties of new polymer-based composites with particular functionalities. Graphene possesses perfect 2D atomic architecture and has a large surface area that boost the bonding, with tailored functional groups on its surface with polymer chains to form high strength composites. Lately, a lot of researchers have concentrated on developing composites with high specific strength, high electrical and thermal conductivities, high impact resistance, excellent energy storage capability and ability to maintain their strength at low-temperature environments using graphene, graphene oxide (GO), reduced graphene oxide (rGO) or carbon nanotube/graphene. The potentiality of using these materials have been explored for high-tech applications in many researches. Furthermore, it has been demonstrated that the use of graphene-based nanofillers does improve the mechanical, interfacial bonding, electrical, thermal and electromagnetic interference shield properties of polymer-based materials. Appropriately, adding a small amount of these nanofillers can make a big changing in the properties of host materials (Hung *et al.*, 2020).

Flexible and controllable self-regulating heating devices have a great potential for use in applications such as soft robotics, healthcare devices, artificial skins and wearable electronics. Conventional self-regulating heating devices are often limited by the rigid nature of the polymer matrices, particularly at high conductive filler concentrations. Recently, this problem has been successfully answered by binary polymer blends that can achieve a desirable combination of mechanical, electrical and pyroresistive properties. Tailored pyroresistive performance and flexibility by presenting a secondary thermoplastic elastomeric phase into graphene nanoplatelet (GNP) filled polymer composites for self-regulating heating devices (Liu *et al.*, 2018). Now, ultimate goals are to design polymer composites that can meet specific requirements for different engineering applications.

Fabrication Methods of Tailored Polymer-Based Composites

To make the aligned carbon nanotubes/hydrogenated nitrile butadiene rubber (CNT/HNBR) composites, HNBR and carbon nanotube bundle (CNTB) were first mixed using a two-roll mill (Zhanjiang Machinery Factory, China). The gap between the two rolls was adjusted to 0.2 mm for high-shear blending, and the vulcanizer (curing agent, weight ratio of HNBR to vulcanizer of 100:1) was added. The CNTs in the aligned mixture were further aligned by shearing for another 10 min on the two-roll mill with the gap between the two rolls adjusted to the smallest value (<0.1 mm). The optimum curing time was determined with an oscillating disk curemeter, and the composite was vulcanized on a platen presser under 15 MPa at 170 °C. For the random CNT/HNBR composites, the CNT/HNBR mixture was cut into slices with the dimensions of $\sim 5 \times 5 \times 1$ mm³. These slices were then collected into a mold and vulcanized on the platen presser under 15 MPa at 170 °C (Liu *et al.*, 2018). The next method is about using graphene and its associated compounds and there are few issues that should be considered in detail to fabricate (GO)/polymer composites. First item is about degree of uniformity of graphene and its associated components dispersed in polymer composites. Next is purity of nanoparticle received from different sources. The third case is interfacial bonding properties between the nanoparticle and surrounding matrix. And the last case is completely removing all solvents in the solution for dispersing nanoparticle in the nanoparticle/resin solution. So, the structural behavior, reliability, and energy storage capability of graphene reinforced polymer composites at different temperature conditions should be focused to assure they are used safely in different engineering applications (Hung *et al.*, 2020).

Another method for fabricating is about tailoring properties *l*-carrageenan nanocomposites. First, cellulose nanocrystals (CNCs) were synthesized through sulfuric acid-assisted hydrolysis of cellulose according to Iglesias *et al.* (2020). Twenty grams of microcrystalline cellulose were hydrolyzed into a 64 wt% aqueous sulfuric acid solution (400 mL) at 45 °C for 30 min under constant stirring of 300 rpm. The reaction was quenched by adding 20-fold cold distilled water. The suspension was washed via centrifugation at 4000 rpm for 15 min. Colloidal cellulose was then obtained after tip sonication at 40% output for 5 min. The

Fig. 1 Schematic diagram depicting ι-carrageenan/CNC nanocomposite film preparation. Adapted from Iglesias, M., Lizundia, E., Costa, C., Lanceros-Méndez, S., 2020. Tailoring electrical and mechanical properties of all-natural polymer composites for environmentally friendlier electronics. *ACS Applied Polymer Materials* 2 (4), 1448–1457.

excess aqueous acid was removed through dialysis for 7 days using a Visking dialysis membrane with a molecular weight cut-off (MWCO) of 12000–14000 Da. Finally, an aqueous CNC dispersion with a pH of 1.9 and a concentration of 1.5 w/w % was obtained. Nanocomposite films were obtained by the doctor-blade technique. First, ι-carrageenan was dissolved in distilled water at 80 °C under a magnetic stirrer for 4 h, whereas CNCs were dispersed in water using an ultrasound bath for 1 h. Then, dispersed CNCs were incorporated into the aqueous ι-carrageenan solution and the resulting mixture was magnetically stirred for 1 h. Finally, single layer films were cast onto clean glass substrates with the aid of a doctor blade (vertically inclined 45°). The process was carried out at a constant rate of approximately 4 cm s^{−1} (equivalent to simple shear rate of 0.6 s^{−1}), where the gap between the blade and substrate was set at 800 μm. The substrate was previously heated at 80 °C with the aim of avoiding a lower solubility of ι-carrageenan arising from a quick cooling of the solution. After room-temperature drying for 24 h, 25 ± 5 μm thick films were obtained (Iglesias *et al.*, 2020) (Fig. 1).

Additives for Tailored Polymer-Based Composites

A much larger dielectric constant than that of polymer composites can be obtained by adding a low content of CNTs to the polymer matrix, with no loss in mechanical properties and processability. One of undesirable properties of CNT/polymer composites is that the large increase in dielectric constant is usually accompanied by an obvious enhancement in dielectric loss, results in largely limiting their applications. Therefore, innovative approaches are required to make dielectric composites with a high dielectric constant and low dielectric loss. One of the common methods to obtain dielectric composites with a high dielectric constant and low dielectric loss is to introduce insulating layers on the surface of CNTs because the insulating layers can effectively stop the direct contact of CNTs with one another. Another way to obtain CNT/polymer dielectric composites with both high dielectric constant and low dielectric loss is to align the CNTs in the polymer matrix, which can reduce the direct connection of CNTs with one another and produce dielectric composites with low direct current (DC) conductivity. The alignment of CNTs in the matrix can be realized by means of electrospinning, microwave curing, liquid crystal-assisted orientation or with the help of external fields like electric, magnetic, and mechanical cases. In particular, the mechanical shearing during traditional mechanical blending can be used to prepare aligned CNT/polymer composites in an industrial scale (Liu *et al.*, 2018).

As mentioned, appropriately adding GO into polymeric matrix could substantially increase the mechanical strength of host polymer materials. Their electrical properties are also improved to prepare the composites more conductive and, further extend their applications to structural capacitors. The GO-coated carbon fiber and carbon fabric have been exhibited strong interfacial bonding properties in composites. Low cost and high effective GO-coated carbon fabric polymer composites demonstrate a great alternative to develop a new generation of carbon fiber (GO/CF) polymer composites (Hung *et al.*, 2020).

The selection of a secondary thermoplastic elastomeric (TPE) phase for adding to a high density polyethylene/graphene nanoplatelets (HDPE/GNP) composites was proved to greatly affect the morphology of the resulting blends, leading to an immiscible binary blend with either a fine or coarse droplet morphology, or a co-continuous morphology, while the location of the conductive nanofiller can be controlled in either one phase or at the interface between two phases (Liu *et al.*, 2018).

Characterizing Tailored Polymer-Based Composites

Composite materials are becoming an inevitable part of our daily lives, as these materials are used for a variety of applications. A better understanding of different properties of composites is very useful in their targeted applications, and therefore the description of composite materials by different techniques plays a major role in the development of durable and high-quality composite products. Polymer-based composite materials provide great flexibility and light weight for the final product. The choice of amplifiers and polymer matrix is crucial in designing a product (Cherusseri *et al.*, 2017).

A composite material is a material that is composed or made of two or more separate phases (matrix phase and dispersed phase), with completely different bulk properties from each of the compounds (Cherusseri *et al.*, 2017). The discontinuous phase is usually harder and stronger than the continuous phase and is called the tailored, while the continuous phase is called the matrix. The matrix holds the reinforcement to create the desired shape while the reinforcement improves the overall mechanical properties of the matrix. Properly covered, it will withstand a great deal of adverse conditions (Deo, 2010). The properties of composites depend on the properties of their constituents, their distribution and the interaction between them. The choice of polymer amplifiers and matrices is essential in designing a product (Cherusseri *et al.*, 2017). The properties of reinforced polymer composites strongly depend on the shape and location of the additive in the matrix. The technology of forming such composites is relatively cheap and easy, in addition, they are suitable for additive-based production. The short CF can be distributed as turbulence in a polymer matrix or it can be oriented. In the latter case, the composites show anisotropy in mechanical, thermal and tribological properties. Among different types of minerals and organics, CFs with relatively low density show the highest tensile strength and elastic modulus. For this reason, CFs, despite their high cost, are widely studied and used. The most promising application of CF is as a reinforcement for polymer-based composites. CF-reinforced polymer composites have been widely used as engineering materials in the aerospace and automotive industries (Chukov *et al.*, 2020).

Various techniques have been used to describe polymer-based composite materials to investigate mechanical, thermal, electrical, magnetic properties, which will be referred to the below sections.

Structural Properties of Reinforced Polymer-Based Composites

Structural polymer-based composite materials (PCMs) are used in different industries: aircraft, missiles, shipbuilding, automotive and electrical industries, construction, sports, chemical and special engineering, medicine, and other applications (Kolosov *et al.*, 2019). This is due to the wide range of physical, mechanical and operational properties of PCM-based materials. For example, such materials combine low density and low modulus of elasticity with high strength and durability and other properties, the shape of the discontinuous phase (which may be allowed by spherical, cylindrical, or rectangular prisms with reciprocal punctures or platelets), and size of the distribution (which controls the texture of the material), and the volume fraction of the interfacial area, all play important role in determining the degree of interaction between the amplifier and matrix. For reinforced applications, structural adhesives should be used. The most common adhesive used in such applications is epoxy due to its excellent adhesion to other materials, but epoxy is brittle. Therefore, by hardening/reinforcing it with other rigid fillers such as carbon nanotubes, fly ash (FA) and milled carbon fiber (MCF), one can mitigate the fragility of the epoxy resin (Kolosov *et al.*, 2019). Recently, CNTs have been used as fillers to increase the strength and values of the composite modulus to enhance the mechanical, physical, and morphological properties of the matrix (Hung *et al.*, 2020).

Structural composites perform excellently in tensile, flexural and impact tests compared to their specimens. Previously, Dutra *et al.* (2000) reported on the performance of a mixture of polypropylene and carbon fibers as reinforcing elements in an epoxy matrix. They discussed the improved properties of hybrids compared to CF-based composites.

Mechanical Properties of Reinforced Polymer-Based Composites

The effects of reinforcement cluster and properties of individual constituents on the overall behavior of the composite under mechanical loading are calculated in terms of effect on elastic modulus and strength. In addition, Chiang *et al.* (2005), Lua (2007), Teodorescu-Draghicescu *et al.* (2009) and Wu (2009) proved that the improvement of mechanical properties has not been successful in all polymer-based composites. The second factors can be considered as an enumerative factor identified, monitored and discussed separately. In material properties testing, flexural strength is usually measured by a 3-point bending test. It has been reported that flexural strength and interlayer shear strength (ILSS) are influenced by the composite design and depend on the position of the reinforcing fiber (Motoc, 2017).

Carbon fiber-based composites have been one of the most appropriate architectures due to some drawbacks of the general reinforcements, including sensitivity to stress concentration due to brittleness, recycling potential and associated production costs. To overcome these weaknesses, the researchers used a combination method with direct cost-benefit and effective properties of materials.

Literatures report on several hybrid/hybrid compounds to be used to exploit the synergistic effects of these compounds among the former. Therefore, Manders and Bader (1981) reported on the flexural properties of carbon fiber and carbon fiber composites. According to their findings, with the relative proportion of carbon fiber decreasing, and with more precise dispersion of carbon fiber, the carbon phase failure pressure increased. They read this behavior as a combined effect and reported an increase in failure pressure of up to 50%. Dynamic mechanical analysis (DMA) is known as a useful tool in studying the behavior of polymer-based composite materials at different temperatures, frequencies or external loading conditions. Measurements can be made using a periodic load to collect the resulting deformation or by applying a fixed load (or a displacement) to obtain creep (or relation) data.

Information on loading modes, calibration methods, sample location, and specific data acquisition can be found in the comprehensive and routine study cited in [Menard \(2008\)](#).

Temperature-dependent dynamic mechanical properties, such as storage modulus, dissipation modulus and mechanical damping (e.g., loss coefficient), allow precise monitoring of the level of interactions (e.g., adhesion) between the polymer matrix and reinforcements. In addition, Cole-Cole or Cole-Davison plots prove to be the most expressive and useful data processing tools in measuring constructive influence. The literature shows a number of sources focusing on fiber-reinforced polymer composites and the properties of their dynamic materials, which show the intrinsic properties of their inherent structure and thermal history during production ([Motoc, 2017](#)). Organic and mineral fibers are considered as high potential reinforcement candidates for various polymer-based composite structures and dynamic mechanical analysis is considered as the most widely used test method to measure the overall behavior of impact and vibration materials. Thermo-mechanical models using temperature-dependent mechanical properties of fiber-reinforced polymer composites were developed around the 1980s. Compression testing of these models has been reported by [Mahieux and Reifsnider \(2001, 2002\)](#). In addition, a Weibull-type function was developed to describe the change in elastic modulus over a range of transfer temperatures. This model is only compatible with thermoplastic materials (e.g., PEEK, PMMA, PPS, etc.) and covers a wide range of temperatures. Other experimental models have been developed by [Gu and Asaro \(2005\)](#). Notably, most researchers have reported on the static and dynamic mechanical properties recovered for their proportional composite specimens. Surprisingly, none of the studies explicitly address the specific issue of similarity between the experimental values recovered from the above configurations, which however, should be the same ([Motoc, 2017](#)).

Thermo-Physical Properties of Reinforced Polymer Based Composite

Uncontrolled thermal expansion in polymer-based composites, especially those designed for structural applications, can cause disturbances that prevent precision of operation in these architectures. To reduce the effects, the constituent can be selected with coefficient of thermal expansion (CTE) at the interfaces or proportionally to vary within a certain range ([Motoc, 2017](#)). References that can be traced in the literatures generally address the issue of thermal expansion in particle-reinforced composites for energy extraction applications, electronic power, electronic packaging, measuring devices, actuators, polymer-based composite architectures for resisting harsh environments ([Motoc, 2017](#)).

Carbon fibers naturally exhibit different CTE responses along their longitudinal and transverse directions and are usually selected as reinforcements for multilayer polymer composite structures to fit their overall CTE. Its fiberglass counterparts, on the other hand, show positive CTE in both longitudinal and transverse directions. By combining “smart” reinforcements, an “ideal” hybrid architecture with zero thermal expansion can be designed. Unfortunately, reality is portrayed beyond these ideal scenarios. Nanoparticles considered as composite structures of polymer particles/composite particles were fabricated and investigated by [Jin and Park \(2012\)](#). In addition to the dynamic and curable mechanical behavior, they controlled the thermal stability of alumina (Al_2O_3) and silicon carbide (SiC) nanoparticles coated with diglycidyl ether bisphenol A (DGEBA) resin, followed by thermal and mechanical properties with increasing the content. Their findings showed that the coefficient of thermal expansion of composite samples in glass and rubber areas decreases with increasing the filler content. Other properties that are studied in the development and description of composite materials are thermal conductivity, especially for various applications such as power electronics, microelectronics, energy storage and storage, sensors and converters and so on ([Alsina et al., 2005](#); [Han and Fina, 2011](#); [Mallik et al., 2011](#); [Otiaba et al., 2011](#)).

Based on the above, a comprehensive work was done by [Lee et al. \(2006\)](#) who investigated various mineral fillers such as aluminum nitride (AlN), wollastonite, whiskers (SiC) and boron nitride (BN) with different shapes and sizes, alone or in combination. Their findings prove the combined effects towards increasing the thermal conductivity due to the advanced connection provided by the filler structure with high aspect ratio. In the next step, the use of larger particles and refined filler surface produce a composite material with increased thermal conductivity. The thermal conductivity of particle-reinforced polymer composites has been extensively studied by [Takei et al. \(1991\)](#), whose theoretical models are among the best predictors of this property of materials. In addition, [Bigg's \(1995\)](#) paper, which extends the above concepts to spherical and irregular fillers, can be studied more comprehensively. In addition, experimental methods, including steady-state and unstable techniques, have been reviewed in the light of heat conduction recovery, especially for applications such as heat exchangers, which are of the primary importance. The thermal conductivity of composite epoxy reinforced composites with particle fillers has been investigated by many researchers, including [Choi and Kim \(2013\)](#) who used aluminum oxide and aluminum nitride fillers, [Teng et al. \(2012\)](#) who addressed this issue using functional multi-walled carbon nanotubes and aluminum nitride or [Zhou et al. \(2010, 2013\)](#) who used hybrid multi-walled carbon nanotube fillers and micro silicon carbide or nano graphite and carbon fillers. [Kandare et al. \(2015\)](#), on the other hand, using recent synergies, reported carbon fiber-based epoxy composites mixed with nanocomposites (e.g., silver and graphene). [Goyal and Balandin \(2012\)](#) also investigated electrically conductive thermal interface materials reinforced with graphene-metal composite fillers. The recovered experimental values showed that graphene fillers are as effective as nanoparticles in increasing thermal properties, and this particular finding is crucial for the thermal management of advanced electronic and optical electronics devices.

[Schuster et al. \(2008\)](#) investigated the thickness and off-plate thermal conductivities of three-dimensional carbon fiber-reinforced polymer composites. Theoretical modeling using finite element method has also been used to increase predictive expressions and their experimental results. In the next step, it can be challenging to consider thermal conductivity as a design aspect with

a diverse fiber architecture that meets mechanical design criteria such as Young's modulus or power. Items listed above were contributed in the shared studies by [Krach and Advani \(1996\)](#), [Kulkarni and Brady \(1997\)](#), [Turias et al. \(2005\)](#). These sources cannot directly address the issue of estimating or predicting effective thermal conductivity, until further developments in this issue are resolved. In general, their aim was to recover the thermal conductivity of polymer-based two-phase composites, reinforced with one-way fibers or mixed, experimentally and theoretically.

Electrical Properties of Reinforced Polymer Based Composite

Because electrical feature is equally important in composite design and applications, and despite the lack of reporting in the literature, knowledge about it has important implications for the optimal design of composites. It is especially important in the construction of functional composites that are structurally different, in that their properties are completely different from those of matrix materials and reinforcements, and they are very different according to the formula of the type of mixed law. Composite materials that have a "coupling" behavior are often referred to as intelligent composites or multipurpose materials ([Motoc, 2017](#)).

First of all, it is necessary to define the meaning of electronic composite, as more broadly defined as a material by [Taya \(2008\)](#): "whose function is primarily to display electromagnetic, thermal and/or mechanical behavior while maintaining structural integrity". Therefore, not only electronic behavior should be examined during studies, but also its physical and pair behavior are required to check. In addition, by referring to the co-authored articles, the developed theoretical models, regardless of the type of amplifiers, shape, size and volume fraction, constitute the deposition mechanism and microscopy. The properties of electronic composites can be tailored to specific applications, such as those in electronic packaging: printed circuit boards (PCBs), thermal interface materials (TIMs), or microelectromechanical systems (MEMS) and BioMEMSs with multiple functions. The intensity of modeling techniques for relaxation processes applied to polymer-based composites can be found. Beyond this shortcoming, [El Hasnaoui et al. \(2014\)](#) randomly dispersed the dielectric properties of epoxy resin matrices with carbon black nanoparticles in varying amounts. The temperature dependence analysis of the electric power using the formulas of Vogel Tammam-Fulcher and Havriliak-Negami showed the existence of carbon black/matrix interaction. Early stages of electronic composite development focus mainly on the use of carbon black (CB) as a conductive filler embedded in a high-density polyethylene matrix ([Vetter et al., 2005](#)) or the combined effect when mixed with carbon fiber in polyethylene mixtures or polyethylene/polypropylene or other polymer matrices ([Motoc et al., 2015](#)).

In addition, the hybrid architecture of particle fibers made from synthetic fibers, including carbon and glass mixed with carbon black, is remarkable. In addition, recent scientific assistance has approached synthetic/natural compounds under the fiber category (e.g., PP/jute blended fabrics) ([Motoc et al., 2015](#)).

Changes in material use patterns and related opportunities along the value chain have made green composites a major topic of intensive research over the past decade. Basically, an insight into the effective dielectric properties of green composite composites is developed. [Jayamani et al. \(2014\)](#) reported on dielectric constant, dissipation coefficient and dielectric loss coefficient of natural jute/bamboo fibers reinforced with composite polypropylene and polyunsaturated composites. In addition, they further argued against the influence of increasing the jute volume fraction on the monitored dielectric properties, in connection with the contribution of the polymer matrix and alkaline treatment of natural fibers.

Potential Applications of Tailored Polymer-Based Composites

These materials have wide strands. About 30% of all custom polymer-based composites produced each year are used in the civil engineering industry. Polymers have good advantages over conventional materials such as light weight, corrosion resistance and ease of processing. They can be combined with fibers to make composites that have reinforced properties, allowing them to be used as members of structures and units. Polymer composites can be found in a variety of forms from structural composites in the construction industry to advanced composites in the aerospace and space satellites industries, as well as in the boating, automotive and rail industries, general engineering, sporting goods, civil engineering, home, and medical applications. Special applications of polymer-based composites include body structure for electric vehicles, wet clutches for torque distribution in car-driven trains and various slip gearboxes, usable space structures, hot-swappable switching, electromagnetic protection, ballistic protection and some other areas. Fiber-reinforced composite materials can have comparable strength to metals and also offer wider range of abilities than metals. The advantages of the polymer (matrix) used for PMC are as follows: obtaining a lightweight material ([Krishna et al., 2016](#)), corrosion resistance, fatigue reduction and good mechanical properties ([Cairns, 2009](#)). The matrix material acts as a fiber alignment as well as a load transformer between the fibers. The strength of the composite increases when using PMC. Matrix material acts as a protection against filler damage ([Crosky, 1991](#)). For this reason, polymer composites have a wide range of applications. Some applications for polymer composites are as follows:

Aircraft is a good example of polymer composites. [Fig. 2](#) shows the polymer composites used in aircraft. These parts include the aircraft frame, protection of the window glass layer (because when the glass is scratched, it increases the risk of breakage and danger to passengers), insulation of electrical parts and aircraft accessories.

Currently, 90% of modern boats are made of PCM, such as fiberglass-reinforced polyester resin. The composition is better both in terms of chemical and mechanical properties of the materials. [Fig. 3](#) shows the boat glass booster and modern polymer fibers used in the structure.

Fig. 2 Fiber-reinforced plastics used in the airplanes (www.pixabay.com).

Fig. 3 Modern boat and polymer fiber glass reinforcement used in the structure (www.pixabay.com).

Fiber-reinforced plastics have been used to reduce earthquake risk in structural applications. The fibers used are either carbon or glass and are used as rods, fabrics, plates and as meshes (Ibraheem and Bandyopadhyay, 2017). Fig. 4 shows how fiber-reinforced plastics have been used in structural applications.

Dental composite is a resin that is reinforced with fillers such as silica, glass and ceramic glasses (Abusallamah, 2010). The reason for using the filler is to improve the wear and fracture resistance of the composite. It is transparent and used for dental cosmetics. A binder such as silane is used to ensure that the filler and resin are completely adhered to each other. Then when the mixture fills the teeth, ultraviolet light should be used to improve the resin composite (Ibraheem and Bandyopadhyay, 2017). Fig. 5 shows a polymer composite used as a filler in dental applications.

Fig. 4 Different kind of structural applications for the fiber-reinforced polymer (www.shutterstock.com).

Fig. 5 Curing the resin composite by UV light using in dental application (www.pixabay.com).

Natural fiber hybrid composites can be a good alternative to synthetic fiber reinforced composites as structural or semi-structural components, especially in lightweight applications (Sathishkumar *et al.*, 2014; Sanjay and Yogesha, 2017; Yusriah *et al.*, 2014). Replacing synthetic fibers with natural fibers in the today's automotive industry can have economic, environmental and social benefits. This part of the research is still of interest to engineers and experts because natural fiber composites can be an alternative solution to ever-degradable non-renewable sources (Hom *et al.*, 2015; Singleton *et al.*, 2003; Zah *et al.*, 2007). These natural fiber composites have been shown to have better electrical resistance, good mechanical properties, good thermal and acoustic insulation properties, as well as higher fracture toughness (Sanjay *et al.*, 2015; Sanjay and Yogesha, 2016; Yelin *et al.*, 2016). Previously explored industrial applications include window and door frames, furniture, rail beds, car and upholstery panels, gardening equipment, packaging, shelves, aerospace applications, leisure, construction and instrument, and sports. In general, these are items that require very high mechanical strength, but instead reduce purchase and maintenance costs (Faris AL-

Oqila and Sapuan, 2014; Ku *et al.*, 2011). Recent work on natural fiber composites shows that the specific mechanical properties of natural fiber composites are comparable to glass fiber reinforced composites. Natural fiber composites, in the form of panels, tubes, sandwich panels, have been used in the last decade to replace wooden fittings and accessories for furniture and soundproof panels (Alves *et al.*, 2010; Mei-po *et al.*, 2011).

Conclusion and Future Outlooks

Polymer matrix composite materials are not a new innovation, but by recent advances, there are many new tailored composites to existence. Also by smart choice of matrix and reinforcement it is possible to make significantly superior materials, with tailored properties for specific applications. In total, with tailored behavior we can achieve more valuable and practical results by changing some properties of polymer composites. Fiber reinforced polymer composites are becoming more common in industry, because of their high specific strength, light weight and ability to be tailored for a specific usage. Fiber reinforced polymer composites are often used as structural components that have to endure extremely high or low heats. The developments in the commercial and feasible applications of composite materials have motivated researchers to create the next generation of composites. New generation of composites purpose to integrate more structural and nonstructural properties into their structure with the aim of enhancing the efficiency of the system as a whole. Polymers, due to their good advantages over other materials such as low weight, corrosion resistance and ease of processing, can be combined with other fibers and composites with reinforced properties. This property increases the scope of application of such material becomes. The main purpose of production cast is to expand the engineering utilization of advanced polymer matrix composite materials and to increase the applications of polymer composites that are used in a variety of fields, including construction, medicine, aerospace, sailing, automotive and rail, general engineering, and sporting goods. Since its initial release, polymers have had a tremendous impact on the society. People live in a world that is almost impossible to imagine without synthetic polymers. But what is the future of polymer science? In our view, the world of the future is unimaginable without polymers: they make a difference, for example in thermal insulation, fibers and clothing, mobility, building materials, microelectronics, green energy production, soil fertility, food packaging, safety, the search for new antibiotics, regenerative drugs, inkjet-based decentralized construction, lightweight composite materials for windmills and electronic mobility, to explore space, just to name a few from a sheer endless list. This social “market” will occupy us, at least for the foreseeable future, and the polymer industry and related labor market will change, but it will still be fruitful and full of opportunities.

Introduction

Radial tyre is a complex structure with highly performance, made up of various types of composite materials. Rubber represents the matrix of this composite structure, to play the major role in vehicle supporting against the road roughness, generating maneuvering forces, providing safety and controlling stability. Because of its nonlinear nature in terms of material and geometry, rubber required many properties to characterize its behaviour.

Many theoretical models have characterized the mechanical behaviour of rubber. These models were developed based on a statistical thermodynamics approach (Treloar, 1973, 1975; Rosen, 1982), which stated that the decrease in entropy arises the elastic force of the rubber. Many research works are mostly focused on developing this approach, which reveals numerous models to characterize the rubber by a quantity known as the elastic strain energy density (W).

A plentiful of constitutive models have been proposed to describe elastomer behaviour, but a few of them are only able to characterize the complete non-linearity response of the material. Clearly, the most important models are those which able to specify the complete behaviours with a minimum number of material parameters, which must be investigated experimentally.

Finite element method based on these models is the most powerful tool which is normally utilized to imitate the static and dynamic behaviour of the tyres in various rolling and cornering states. In the last two decades, researchers used the commercial software of finite element to simulate the tyre dynamic problems. Goldstein (1996) utilized the Abaqus codes to mimic the radial truck tyre in slow rolling subjected to three dynamic cases. The conditions were, straight free rolling, braking, and cornering. Another software, LS-DYNA3D, was used by Kao and Muthukrishnan (1997) to simulate the tyre dynamic response for simple tyre model coupled with rigid wheel model. They revealed that, the dynamic behaviour of the tyre can be predicted from the design data, geometry, layout, material properties of various components, fiber reinforcement of the tyre, etc. The constitutive model of Mooney was adopted to describe the elastic properties of the rubber, while the strain energy function derived for the fiber-reinforced rubber were used to calculate the carcass properties. The calculated rim reaction forces agreed well with the experimental results.

Koishi *et al.* (1998) simulated the tyre cornering problem using an explicit finite element code, PAM-SHOCK, for the passenger tyre of size 175SR14. The research demonstrated the feasibility of the proposed simulation. To assess the accuracy of the model, the experimental results from the tyre test system, MTS Flat-Trac, were compared with the predicted results. The calculated cornering forces agreed well with the experimental results.

Campanac *et al.* (2000) studied the vibrations theories of the rolling tyre. They had introduced the heterogeneity produced by the tread pattern on the tyre belt in studying the vibration of the tyres, and showed that the tyre vibrations could be described by linear equations with time periodic coefficients.

Shiraishi *et al.* (2000) simulate the dynamic behaviours of a rolling tyre by an explicit finite element method. The complicated construction of the tyre was modeled exactly. The authors investigated several tyre properties for various rolling conditions. The findings showed that, there was a good agreement between the calculated and experiment results.

Kabe and Koishi (2000) had conducted a simulation of tyre cornering using codes of implicit and explicit finite element analysis. Where implicit finite element analysis represent the steady-state cornering simulation, and explicit described transient cornering simulation. The technique of moving reference frame for the case of implicit simulation required fine meshing in the contact area only. While, the fine meshing was also required in the circumferential direction of the tyre for explicit analysis. The predicted results were compared with experimental results. Good correlations were obtained between the predicted and measured data.

In this work, finite element model of a passenger tyre using Abaqus software was built to predict the dynamic performance of the tyre containing modified tread material. The material properties of the model are based on data extracted in the laboratory for the tread blend containing different particle size of waste tyre crumb rubber 40, 150, 180, 250, 425 and 600 μm at different weighted percentage 10%, 20%, and 30%. The crumb rubber of waste tyre is working as a virgin rubber replacement material. The proposed code should be able to analyze the tread performance when it becomes part of a real tyre structure.

Fig. 1 Result transfer analysis sequence.

Modelling Method

The tyre was modeled in Abaqus using the technique of symmetric result transfer. This technique provides the ability to transfer results obtained from two-dimensional axisymmetric model or a partial three-dimensional model to full three-dimensional model. The capability of results transfer can considerably simplify and reduce the time and cost of the analyses of complex structures. According to this procedure, tyre simulation can be broken down into three separate analysis, axisymmetric two-dimensional model, partial three-dimensional model and full three-dimension model as shown in [Fig. 1](#).

The first simulation exploit the symmetry of the tyre model to use half cross section area of the tyre. This part of simulation was used to investigate the effects of inflation on the strain and stress component of the tyre elements. A complete two-dimensional result was extracted at the end of this step, and transferred to the second part of the simulation. This part is referred as a two-dimensional axisymmetric model.

The two-dimensional axisymmetric of the tyre cross section was revolved about the axis of revolution to produce the partial three-dimensional model, which is the second model of simulation. This part of simulation entails computation of static deformation shape of the inflated tyre under the vehicle dead load.

In the last part of the analysis, the result from the partial three-dimensional analysis was transferred to the full three-dimensional model. A complete tyre was produced by combining the two part of the partial three-dimensional model; one is the original part from the previous analysis and the second from the reflection of the partial three-dimensional model about the tier centerline. The effect of tread material modification on the tyre rolling performance was investigated during this analysis. The model is referred to as a full three-dimensional model. [Fig. 2](#). shows complete steps layout of three-dimensional analysis of rubber tyre utilizing the result transfer capability in Abaqus finite element software.

Tyre Material Simulation

The reinforcing materials used in the radial tyre structure were simulated as linear elastic materials and the required information was density, modulus of elasticity and poison ration for the steel cord belts and carcass, while the tread was modeled as hyperelastic materials with test data extracted from the mechanical test for each tread blend. The geometrical specifications such as direction, cross section area of the steel cord and spacing between each cord are also important to specify. The bead component was treated as a rigid body material. Material properties and dimensions used in this work are listed in [Table 1](#).

Fig. 2 Layout of complete steps of tyre analysis using Abaqus finite element software.

Steps of Simulation

The first step of simulation analysis uses the symmetry of the tyre geometry and utilizes the result transfer capability to simulate the effect of uniform internal pressure. The tread and sidewall components are made of rubber and the carcass and belts are made of rubber composite reinforced by textile fiber and steel cord respectively. The rubber is modeled as incompressible hyperelastic

Table 1 Reinforcing material specification

Component	Density ρ (Kg/m ³)	Modulus of elasticity E (N/m ²)	Poisson ratio ν	Area per bar (m) ²	Spacing (m)	Angle
Carcass textile	1500	9.87E9	0.3	4.208E-7	0.001	0

**Fig. 3** Axisymmetric model mesh.

material. For the entire section, elements type of continuum, generalized and axisymmetric type with four and three nodes hybrid (CGAX4H, CGAX3H) was used. While, the belts and carcass were modeled as surface elements of type (SFMGAX1) **Fig. 3**.

The second step of simulation is the foot-print solution of the tyre named as partial three-dimensional simulation. The code of "SYMMETRIC MODEL GENERATION" provided by Abaqus was used to generate a three-dimensional model from the set of element and nodes in the two-dimensional axisymmetric model as shown in **Fig. 4**. Element types of C3D6H and C3D8H were used corresponding to the two-dimensional element type. The boundary conditions applied to this part of simulation represent the displacement and the dead load that the tyre undergoes in the static condition. In this analysis, only half of the tyre was simulated; due to that reason, the load applied will be half of the total load carried by the tyre. For passenger tyre, the weight of the vehicle was divided into four, and half of this weight force will be used as the vertical load applied to the wheel center.

The last part of tyre analysis is three-dimensional model simulation, where the footprint results from the previous analysis is transferred to a full three-dimensional model. The two partial three-dimensional models (one part is the original part and the other part is the reflected one by "SYMMETRIC MODEL GENERATION" code) are combined together after reflecting the original mesh over the tyre center line **Fig. 5**.

Fig. 4 The generation of partial three-dimensional model.

Fig. 5 Full three dimensional model.

The boundary conditions for the static solution of this step are inflation pressure (200 kPa) at the nodes of inside surface, and vehicle weight force (3300 N) applied to road reference node, while the dynamic boundary conditions are ground speed of 80 km and 3° slip angle.

The steady-state transport capability in Abaqus has been used in this model. This technique utilizes moving reference frame method in which Eulerian manner describes the rigid body rotation and Lagrangian manner describes the deformation region of the tyre. This kinematic description changes the contact problem of the steady state moving to pure spatially dependent simulation. Therefore, the mesh needs to be refined only in the contact region.

Mesh convergence was calculated based on maximum stress generated in the tyre during the rolling and cornering state with the total element number of (17425) as shown in Fig. 6.

A dynamic experimental data published by Kabe and Koishi (2000) was used in this study to verify the proposed finite element model. The collected data for radial tyre of passenger car's of size 235/45ZR17 was used. The tyre model was in contact with the road under a vertical load of 4 kN and traveling at 10 km/h (2.7778 m/s). The angular velocity of the tyre varied from 8 to 10 rad/s in order to determine the free rolling radius. The free rolling radius was estimated to be 313.28 mm. The cornering force generated at slip angle of 1° , 0° , and -1° were measured experimentally, and compared with the predicted values produced by the finite element model Fig. 7. Fig. 8 shows the cornering forces versus step time history at different slip angle produced by Abaqus

Fig. 6 Maximum stress convergence value.

Fig. 7 Cornering force during analysis step time at (a) (-1°) slip angle, (b) (zero) slip angle, (c) (1°) slip angle produced by Abaqus.

Fig. 9 Rolling force at rim in braking traction and slipping.

software. Fig. 9 shows a comparison between the experimental values and those calculated by Abaqus. The nonzero cornering force obtained at slip angle of 0° on both experiment and finite element is caused by play steer force due to the an isotropy of steel belt. The figure indicates that the calculated results by the Abaqus code agreed well with the experimental results.

Results and Discussion

In this research, the mechanical properties data of the material for different tread blends with different crumb rubber content and particle size, which were produced in the library, have been used to investigate the effect of tread layer properties on the tyre dynamic performance. The materials properties of each tread blend were introduced to the simulation model by test data option, which is available in Abaqus material section.

Hence, this model was used for all of the tyre tread blends under investigation. Tread blends with crumb rubber contents of 10%, 20% and 30% were investigated. Furthermore, the effect of crumb particle size of (40, 100, 180, 250, 425 and 600) μm was also studied. The material properties of other part of the tyre have been selected from the literature (Systèmes, 2012; Koishi *et al.*, 1998).

The rolling force, which is the reaction in the moving direction in braking and traction analyses, are shown in Fig. 10. The time of first step (1–2 s), represent the rolling reaction at 80 km/h, while the time of second step (2–3 s) represent the 3° cornering effect.

The effect of CR content and particle size on the axial force for the braking conditions is illustrated in Fig. 11. The figures show same behaviours for rolling resistance occurred in axial reaction forces. These behaviours can be explained by the raising of the modulus of elasticity with the reduction in CR content and particle size, which was determined from mechanical property test of the tread blend.

The strain energy for the whole system during the rolling and cornering condition for the braking and traction state is shown in Fig. 11. The value of strain energy in the static step was due to inflation and vehicle loading effect (step time from zero to one second). This value is reduced as the tyre starts rotating in the rolling step; this is due to the reduction in vertical load effect because of tyre inertia. The value of vertical force is a resultant of contact vertical reaction and vertical acceleration of the tyre mass (Captain *et al.*, 1979). As such, the force balance at the tyre axle in the vertical direction can be written as:

$$F_z = F_v - m\ddot{z} \quad (1)$$

Fig. 10 Effect of loading and particle size of CR on the axial reaction at tyre rim at breaking.

Fig. 11 Strain Energy density for the whole tyre model in the steps of rolling and cornering.

Where F_z is a vertical force at the tyre axle, F_v is a contact vertical reaction at tyre footprint; m is the mass of the tyre.

The value of strain energy increased as the tyre started rolling either in braking or traction state to reach its maximum value at the end of cornering step. While rolling, circumferential and lateral bending occurred due to the effect of the contact region. Thus, a frequent compression and stretching of all of the tyres layers accrued. The circumferential stress and strain during the rolling step are considered as a major contributor to inter laminar shear stress and strain, which leads to produce a propagated strain energy density within the rolling step (Chang *et al.*, 2003). The cornering state increases the strain energy slightly due to the addition of lateral force effect (Koishi *et al.*, 1998).

Figs. 12 and 13 present the effects of particle size and content of CR incorporated in the tread layer on the whole tyre strain energy at traction and braking state. The figures show that as the content and particle size of CR reduced the strain energy increased, and the content of 10% CR produce a higher rate of increase in comparison to the rate between 20% and 30%.

The force per unit area applied on the tyre surface in the contact patch can be decomposed into normal to ground component and tangential to the component. The normal component is a contact pressure. The contact pressure between tyre and road plays an important role in the design of tyres and roads through its major effects on the shear and normal stress in the contact patch to provide the desired driving or braking force (Marshak *et al.*, 1986). The distribution of contact pressure under rolling and cornering state for braking and traction conditions is shown in Fig. 14. The figure shows that for all cases, the maximum contact pressure is located in the shoulder zones with the rear region of the braking state Fig. 14(a), and front region with traction state Fig. 14(b). The cornering case shifts the maximum pressure toward the slipping direction to form a new force balance produced by the friction between tread and ground. These behaviours coincide with that stated by Narasimha Rao and Kumar (2007). The value of maximum pressure increased in the case of cornering due to the effect of contact area reduction through the slipping case; see Fig. 14(c) and (d).

Fig. 15 shows the comparison of the pressure distribution along the longitudinal contact patch, in the cases of braking and traction. The figure also shows that the peak pressure in the case of traction appeared in the front region to produce the required traction force, while in the case of braking, it appears at the rear region to create an opposite braking torque. The same behaviours was shown by Dorsch *et al.* (2002).

Fig. 12 Effect of CR particle size and content on the whole tyre strain energy at traction state.

Fig. 13 Effect of CR particle size and content, on the whole tyre strain energy at braking state.

The effect of CR content used in tyre tread blend on the pressure distribution is shown in Fig. 16. The pressure increased with lower CR content in the tread blend due to the enhancement in the mechanical properties as the CR reduced, which produced better traction and braking stability. Same behaviour has been found for CR particle size as shown in Fig. 17.

The deformation behaviour of tyres in any direction x , y and z to the applied loads are important characteristic in tyre dynamics. This deformation depends mainly on the tyre stiffness in each direction and the value of applied load (Jazar, 2008).

$$F_x = k_x U_x \quad (2)$$

$$F_y = k_y U_y \quad (3)$$

$$F_z = k_z U_z \quad (4)$$

Where, F_x , F_y and F_z are the external forces on the tyre with k_x , k_y , k_z as tyre stiffness in each direction and U_x , U_y , U_z are the tyre strain in three directions.

In this work, the deformation has been measured at the contact patch where the maximum strain existed. The magnitude of strain vector has been taken into consideration to compare the effect of the different parameter on the tyre performance. Fig. 18 provides a contour plot for the deflection values which occur at the tyre during the rolling and cornering state of 80 km/h. As expected the maximum strain value is located at the contact patch which represents the elements that are subjected to maximum compression, tension and shear stress. As such, the deflection values for the elements along the contact patch were plotted in Fig. 19. The figure shows that there is a slight increase in the strain value when the content of CR in the tread layer increased. This is because of the reduction in CR content that produced higher stiffness of tread layer. Finally, the effect of braking and traction state has been illustrated in Figs. 20 and 21 respectively. From these figures, it is clear that the peak of strain is shifted towards the moving direction due to the position of maximum footprint pressure illustrated in Fig. 14. The cornering force applied to the moving tyre produced additional strain as shown in Fig. 21 where the value of strain increased from 23.3 mm for the rolling state to 28.3 mm for the cornering state.

Conclusion

Many theoretical models from previous researches have characterized the mechanical behaviours of rubber. These models were utilized by finite element software to evaluate and simulate the hyper elastic material behaviours. A complete analysis based on Abaqus codes was performed for passenger tyre with special concern on the tyre tread behaviours. The experimental mechanical data for the tread blends at different CR particles size and contents were used to investigate the static and dynamic effects of using different CR in the tyre tread. The finite element code has proved efficient in simulating the effects of CR incorporation in tread blend. The code is capable of investigating the effects of material and shape design of any part of the tyre structure. The outcomes from the FEA model showed that the finer particle size of crumb rubber might increase the rolling resistance up to 2.5% as compared to a particle with coarse size. The low content of CR showed higher rolling resistance in braking and traction case. The analysis shows that the maximum strain energy was accrued at the finer CR size and lower contents. The model also helped in showing the maximum contact pressure regions in the cases of braking, traction and cornering.

Introduction

For conductive ink, there are two types of liquid with different viscosity and functionality that serve to carry the nanoparticles, namely the binder and the hardener. Epoxy is used as binder in this study and it is compatible with the viscosity behaviours of the ink. It shows the anticorrosion properties when acting as coating ingredients. While for the hardener, it is an additional substance to the ink mixture to produce strong or more durable ink finish and as well as the curing agent for epoxy. The final result of mixing these three components is a conductive ink that maintains its liquid form until it is printed on a surface at its drying point and able to conduct electricity.

In this study, troubleshooting problems in the characterization of conductive ink are elucidated in order to fabricate conductive ink which has high conductivity tracks or patterns. The characterization of conductive consists of the involved parameters, the formulation of ink loading, the printing procedure, ink-substrate interaction, the temperature to cure and post-treatment of ink.

For the formulation of ink loading, the interaction between filler, binder and hardener is important as it is the preliminary step to find out which ink loading can produce high conductivity. The ink loading is printed on the glass substrate, and then they will go through preheating method where the ink loading is cured in the oven for specific time and temperature. The characterization of conductive ink is investigated so that a proper understanding may be gained through various methods (analysis); four-point probe for sheet resistivity, contact profilometer for surface texture and light microscope for morphological analysis.

All these described steps are repeated for the ink loading in accordance to the composition of element to produce conductive ink. This study highlights two research questions about the formulation of silver nanoparticles-filled epoxy to produce conductive ink and the relationship between all of the investigated parameters for silver nanoparticles-filled epoxy.

The method of fabricating electrical circuits with the use of conductive ink will take place by using current method of creating circuit boards. The conductive ink depends on the formation of metal nanoparticles. Thus, the issues that need attention are the materials composition and its behaviour to have high conductivity ink as the drawback to conductive ink circuits is their resistance.

Crucial success factor for quick, simple and affordable production of PE prototypes and electronically functional prints is by choosing the accurate ink loading. One of the issues where the ink loading needs alteration is when the conductive ink is not fully dried after curing at certain temperature. Another issue is the ink-substrate interaction; the ink can easily come off of the substrate after printing or curing process, which indicates that a compatibility issue may come in between the ink and substrate, or the ink may not be dried adequately.

Recently, most researchers around the world studied the effect of conductive ink for silver nanoparticles-filled epoxy by implementing measurement techniques to conductive ink in order to maximize the quality and reliability of conductive ink through three techniques (Samano, 2017). These described techniques are sheet resistivity, surface texture and morphological behaviour for sheet resistivity. Samano described that four-point probe can measure the sample by producing no error with test lead resistance. Next, for the surface texture measurement, roughness is found as one of the main contributors that affect the electrical resistivity of printings on the substrate (Maattanen *et al.*, 2010) and imaging method from conventional microscope can contribute image with fine details that includes elemental details of printed sample (Ikeda *et al.*, 2007).

Based on these reports, all of the rising issues of the conductive ink are linked to the formulation of ink loading. It is also important to be mentioned about another additional factors such as material selection, printing method, curing temperature and others. Therefore, this study can potentially come out with the solutions for the stated problems.

This article discusses about the overview of surface roughness effect on silver nanoparticle filled epoxy composites for electronic packaging. Both directions, which are vertical and horizontal will be discussed in order to evaluate the surface roughness, and at the end of the study one conclusion is made.

Silver as Nanoparticle Materials

For the purpose of this article, only silver nanoparticles material is the subject being highlighted. Joshi (2011) and Burton (2008) described that silver maintains its reputation as the first option of end-users despite the fact that it is the most high-priced material in-use. It is due to the benefits of its high conductivity, even when oxidized as well as it can be simply formulated into inks and its adhesive properties toward substrate is better than nickel and copper.

Table 1 Metallic track comparison

	Sintering temperature	Thickness control	Ink stability (Clogging)	Solvent composition
Nanoparticle Inks	> 150°C	Deposition layers	Poor	Multiple
MOD Inks	70–130°C	Deposition layers	Good	Binary
Catalyst Inks	25–100°C	Reaction times	Excellent	Single
Reaction Inkjet System	Room temperature	Reaction concentration	Excellent	Single

In terms of printing conditions, inks must have high amount of silver and require sintering temperature of 150°C (Mosicki *et al.*, 2005). Allen stated that the printed patterns of nanoparticles inks with high resistivity need a process of sintering at elevated temperatures (100–200°C at 30–60 min) to distinguish stabilizers and/or some electrically non-conductive organic components to improve conductivity (Allen *et al.*, 2008).

Previous researchers were tabulated the benefits and drawbacks of nanoparticle inks as compared to other inks are listed in the Table 1.

Conductive Ink Characterization

Merilampi explained that the purpose of the characterization of conductive silver ink is to find out the parameters that can be improved in order to accomplish the desired properties of the ink in accordance to the conditions decided by different applications in 2015.

Electrical Properties

Joshi (2011) explained that the material resistance, which against the electric current flow is influenced by the dimensions of materials (the shape, length and area of cross sectional) and material chemical composition. Joshi added that the resistivity with SI units of Ohm-meter is corresponding to the conductivity with SI units of Siemens/meter.

The resistivity of the samples traces can be described as Eq. (1),

$$\rho = \frac{RA}{L} \quad (1)$$

where ρ is the resistivity, A is the cross-sectional area of the ink, L is sample trace length from end to end and R is the resistance recorded from the multi-meter.

The measured values of resistance after each sample being dried were used for the next calculation for resistivity of the sheet by the Eq. (1),

$$R_{SH} = R \times \frac{W}{l} \quad (2)$$

where l is the length of line in mm, W is the width in mm, R is the resistance in Ohm (Ω) and R_{SH} is the resistivity of the sheet in Ohm/sq, Ω /sq.

According to Nash *et al.*, the resistance of patterns was determined by using a four-point probe; when the probes were positioned on each of the lines, the current between the outer pins was set to $I = 100$ mA, and the voltage V across the inner pins being recorded. The resistance per unit length (l) was obtained by:

$$\frac{R}{l} = \frac{V}{I} \quad (3)$$

where the resistance per unit length is multiplied by the cross-sectional A in order to obtain the resistivity (Nash *et al.*, 2015).

Conductivity Versus Temperature

In 2008, Perelaer claimed that the conductivity will increase with the formation of an on-going percolation network throughout the printed pattern and the presence of metallic connection between the particles. Maissel added that the presence of a thin (as of a few nano-metres) residual organic layer among the particles of silver is adequate to avoid the movement of electrons between the particles in 1970. A rise in the temperature can distinguish the adsorbed dispersant that is possible to remain on the particles' surface (Perelaer *et al.*, 2008).

To acquire the possibly lowest resistance of the printed patterns, Perelaer proposed that the process of sintering is needed to convert the initial tiny contact regions to thicker necks, and finally to a dense layer. It is proved by Kim and Moon (2005) that the higher temperature causes the neck size to grow by adding densification. Thus, while this process is carried out, the connections among the particles become wider, which lead to the increasing of conductivity.

Research Methodology and Materials

The surface roughness of the sample can be identified by using portable contact profilometer. The measurement was taken at the same spot as microscopy and electrical were used as shown in Fig. 1.

Each substrate has two samples of ink layers located side by side that was labelled as Position A and Position B. Furthermore, every position is divided into three regions; Region 1, Region 2 and Region 3. The measurement took place at each region, but in the case of measuring the surface roughness, the measurement was taken in two directions, which were vertical and horizontal direction. Fig. 2 illustrates the region and direction of surface roughness measurement, and Fig. 3 shows the sample point of the measurement.

For the measurement of surface roughness, the sensor was put on the surface and then uniformly moved along the surface by driving the mechanism inside the instrument. Through the sharp built-in probe, the sensor captures the roughness of the surface. The roughness generates probe displacement, which causes the change in inductive quantity of induction coils and produces analogue signal. It is in the part of the surface roughness at output end of phase-sensitive rectifier. The signal then enters the system of data collection and these collected data are processed with parameter calculation and digital filtering by the chip. After that, the results are being displayed on LCD screen. The sample probe is shown in Fig. 4.

Before measuring the surface roughness, suitable probe of the sensor must be chosen since there are two types of probe either for flat surface or curved surface. Then, the sensor must be installed into the connection sheath located at the bottom of the instrument before the measurement is carried out. The probe is the major part of the instrument and acquires careful handling during the installation and unloading. It cannot be touched so as to prevent disturbance to the measurement data.

After the installation, the instrument was switched on and the related surface of the part was made sure to be clear. The instrument was placed (Fig. 5) stably and correctly on the surface to be measured and its position including the height was adjusted so that the pin of the probe to be in contact with the surface. The sliding trail of the probe must be parallel to the direction of process line on the surface according to the required directions; vertical or horizontal.

Fig. 1 Sketch of sample.

Fig. 2 Region and direction of measurement.

Fig. 3 Measured sample.

Fig. 4 Instruments and sensor.

Fig. 5 Positioning the instrument.

Then, the Start key was pressed to start the measuring process and the pin was let to finish the sliding. While the pin was sliding, the instrument and the sample must be held firmly to avoid them from moving around; otherwise the movement may cause the reading to be “out of range” displayed on the screen. After the sliding finished, the data was filtered and the instrument automatically stored the results; hence, displayed them on the screen.

Results and Discussion on Surface Roughness

In this study, Gökkaya and Nalbant explained that the parameter of surface to assess the surface roughness is the average of roughness, Ra that is also recognized as the centre line average (CLA) or arithmetic average (AA). The roughness average (Ra) is the integral of absolute value of profile roughness height over the length of evaluation, or the region between its centre line and profile of roughness (Gökkaya and Nalbant, 2007).

Surface Roughness in Vertical Direction

The results of the surface roughness for measurement in vertical and horizontal directions are shown in the table. All other parameters are remained constant so that only the surface roughness effect can be merely obtained. The vertical direction results are shown in [Table 2](#).

Each of the data is translated into the graph that represents three types of relation; relationship between surface roughness and number of measurement taken on the same spot, relationship between Ra and point of measurement and relationship between total Ra and measurement points at both positions. The details analysis of vertical results is shown in [Table 3](#) for 10% filler, [Table 4](#) for 20% filler, [Table 5](#) for 30%, [Table 6](#) for 40% filler, [Table 7](#) for 50% filler, [Table 8](#) for 60% filler, [Table 9](#) for 70% filler, [Table 10](#) for 80 % filler and [Table 11](#) for 90% filler, respectively.

Table 2 Vertical direction results

% of filler	Position	Surface roughness (μm)

Table 3 Analysis of vertical results for 10% of filler

Vertical Results	Analysis
Sample A at Point 1  Position A It has low surface roughness that is in the range of 0.2–0.25 µm, which means that the result has stable consistency.	
Sample A at Point 2  The graph illustrates low surface roughness where the range is 0.25–0.3 µm, but it increases as compared to the previous point.	
Sample A at Point 3  This area has the lowest surface roughness that is in the range of 0–1 µm, which means that it has the smoothest surface.	
Average Sample A  At point 3, Ra between three points is the lowest as compared to the other two points, but the sample still has smooth surface. The error bar appears to be short since the difference between the highest and the lowest values at each point are 0.041 µm, 0.021 µm and 0.018 µm.	
Sample B at Point 1  Position B It has the highest surface roughness value as compared to other points in both positions, but in consistent range.	

Sample B at Point 2

The graph illustrates low surface roughness with small gap of value between the times of data reading.

**Sample B at Point 3**

It has the lowest surface roughness value as compared to the value in this position. At third reading when the data is taken, the value slightly increases.

**Average Sample B**

At the first and second points the data is taken, Ra is consistent while at the third point, the value decreases, but the sample is still in homogenous solution since the value gap is small. The error bar appears to be short since the difference between the highest and the lowest values at each point are 0.034 µm, 0.019 µm and 0.038 µm.

**Total Average A & B***Total average at positions A & B*

At point 1 and 2, total Ra is consistent while at point 3, it decreases in value but in small gap, which describes that the sample is in homogenous solution. The error bar can barely be seen, which proves that the total average values are more certain.

Table 4 Analysis of vertical results for 20% of filler

Vertical Results	Analysis
Sample A at Point 1 	<i>Position A</i> It has the highest value of surface roughness for 20% of filler, which is in the range of 0.7–0.9 µm.
Sample A at Point 2 	The value of surface roughness is consistent since the gap of value between the reading times of data taken is small.
Sample A at Point 3 	The graph illustrates the lowest surface roughness value at this position with the range of 0.12 µm until 0.18 µm.
Average Sample A 	There is decreasing of Ra from the first reading to the second and third readings with the difference in Ra value between the first and second reading is 0.46 µm. The error bar is in small dimension, which coming from the difference between the highest and the lowest values at each point with the values of 0.055 µm, 0.011 µm and 0.057 µm.
Sample B at Point 1 	<i>Position B</i> Graph illustrates that the value of surface roughness is the highest at this position where the data is 0.5 µm and above.

Sample B at Point 2

From the graph, the data from third reading shows slight decrement of surface roughness value.

Sample B at Point 3

Graph illustrates that it has the lowest value range of surface roughness, which is below 0.1 μm where the graph shows the consistency between the data.

Average Sample B

The same as at position A, Ra starts to decrease at point 1 from 0.689 to 0.229 μm; but between point 2 and point 3, there is small difference in their data. The error bar can barely be seen since the difference between the highest and the lowest values at each point are below 0.04 μm.

Total Average A & B*Total average at positions A & B*

The graph displays similar condition with Average Sample A and Average Sample B where at the first point; total Ra starts to decrease but consistent at point 2 and point 3. The error bar can barely be seen, which proves that the total Ra values are more certain.

Table 5 Analysis of vertical results for 30% of filler

Vertical results	Analysis
Sample A at Point 1  Position A From the graph, the data can be seen to have the consistency since the difference of surface roughness value between reading time is small.	
Sample A at Point 2  The graph also shows consistency since the gap between the surface roughness values is small but there is slightly decreasing value at third reading.	
Sample A at Point 3  The data displays slight difference among all of the three readings since the range between the highest value and the smallest value is small.	
Average Sample A  Through the graph, Ra starts to increase from Reading 2 to Reading 3 with the difference value of 0.836 μm while the data keeps consistent between the first and second readings. The error bar is in small dimension, which coming from the difference between the highest and the lowest values at each point that is 0.107 μm and below.	
Sample B at Point 1  Position B The graph is consistent since there is no big difference between their values of surface roughness.	

Sample B at Point 2

At first and third readings, the data is consistent, but for second reading, the data is a bit decreasing in value.

Sample B at Point 3

The graph also has the same condition as at point 1 where the difference between the values of surface roughness is small.

Average Sample B

As can be seen in the graph, the Ra value from second reading has obvious difference as compared to the average value from first and second readings. The difference value between Reading 1 and Reading 2 is 0.693 µm while between Reading 2 and Reading 3, the difference value is 0.709 µm. Thus there is no consistency in their values. The error bar is in short dimension, which is caused by the highest value is 1.171 µm and the lowest value is 0.424 µm.

Total Average A & B**Total average at positions A & B**

The total of Ra keeps increasing across the three points, but at point 2 and point 3; they have small gap in data. The error bar can barely be seen, which proves that there is small difference between the average values.

Table 6 Analysis of vertical results for 40% of filler

Vertical Results	Analysis
Sample A at Point 1  Sample A at Point 2  Sample A at Point 3  Average Sample A  Sample B at Point 1 	Position A The value of surface roughness at this point is the highest for 40% of filler, which ranges up to 0.8 μm. The graph shows small increment of value at Reading 3 as compared to two other remaining readings. The data displays up to no difference among all of the three readings since their values are around 0.3 μm. Ra value is the highest at point 1 but the average value starts to decrease at point 2 and point 3. The error bar can barely be seen since the difference between the highest and the lowest values at each point is not exceeding over 0.12 μm. Position B The value from the second and third readings shows consistency but differs from the value at Reading 1 that has lower value as compared to the other two values.

Graph displays consistency among all of the three readings lead by the small difference in their values of surface roughness.

The graph illustrates that it has the lowest value of surface roughness for this sample that is in the range of 0.2–0.3 µm.

From the graph, the data shows consistency among the three readings, which proves that there is up to no difference in Ra values. The error bar can barely be seen, which proves that there is small difference between the average values.

Total average at positions A & B

Total average values at point 2 and point 3 show consistency but they are lower as compared to the total value of Ra at the first point. The error bar can barely be seen, which explains that the total average values are more certain.

Table 7 Analysis of vertical results for 50% of filler

Vertical Results	Analysis
Sample A at Point 1  Position A The graph exhibits a stable consistency among the values since the difference in their value of surface roughness is up to no difference at all.	
Sample A at Point 2  The graph also experiences the similar situation as in the previous graphs where the data being displayed has small difference.	
Sample A at Point 3  The values from Reading 1 and Reading 2 are consistent but at Reading 3, the value is slightly increasing.	
Average Sample A  From Point 3, the increasing average value is obvious while the average values at Point 1 and Point 2 are consistent. The error bar can barely be seen which causes by the difference between the highest and the lowest values at each point is only up to 0.03 µm.	
Sample B at Point 1  Position B From this point, it has the lowest value of surface roughness for 50% of filler and exhibits the consistency in their values as can be seen in the graph.	

Sample B at Point 2

The graph also displays that the values of surface roughness at this point have stable consistency.

**Sample B at Point 3**

The graph illustrates that the values of surface roughness among all of three readings also have consistency.

**Average Sample B**

At Point 3, the average value is at its highest while the rests show small up to no difference in their average values. The error bar can barely be seen due to the difference between the highest and the lowest values at each point is only escalated up to 0.03 μm.

**Total Average A & B***Total average at positions A & B*

The total average values for all of three points have small difference but the total average at point 3 is a bit higher as compared to other points. The error bar can barely be seen, which describes that the total average values are more certain.

Table 8 Analysis of vertical results for 60% of filler

Vertical Results	Analysis								
Sample A at Point 1 <table><thead><tr><th>Reading</th><th>Surface Roughness (μm)</th></tr></thead><tbody><tr><td>1</td><td>3.5</td></tr><tr><td>2</td><td>3.7</td></tr><tr><td>3</td><td>3.7</td></tr></tbody></table>	Reading	Surface Roughness (μm)	1	3.5	2	3.7	3	3.7	Position A The values rapidly increasing from the previous percentage of fillers where they start from 2 μm and above. From the graph, the values at Reading 2 and Reading 3 are consistent while at Reading 1, the value is a bit lower.
Reading	Surface Roughness (μm)								
1	3.5								
2	3.7

Reading	Surface Roughness (μm)								
1	5.1								
2	5.1								
3	5.0								

Sample B at Point 2

At this point, the value of surface roughness is the highest for this sample with the range of 5.2–5.3 μm .

Sample B at Point 3

It has the lowest value of surface roughness for 60% of filler that is in the range of 2.3–2.8 μm while the data shows consistency in their values.

Average Sample B

The average values at point 1 and point 2 have small difference but the value drops rapidly at point 3 as can be seen in the graph. The error bars show long dimension, which means that the concentration of calculated average values is low.

Total Average A & B*Total average at positions A & B*

The total average value at point 3 has big gap as compared to the values at point 1 and point 2 as it experiences high decreasing of value. The error bar displays big difference, which means that the total average values of surface roughness are uncertain.

Table 9 Analysis of vertical results for 70% of filler

Reading	Surface Roughness (μm)								
1	5.0								
2	5.2								
3	5.1								

Sample B at Point 2

Graph has the lowest surface roughness value for 70% of filler and the value from Reading 1 is the lowest while the values at Reading 2 and Reading 3 are consistent.

Sample B at Point 3

The data produces a consistent graph plot since there is small gap between all of the surface roughness values.

Average Sample B

The graph exhibits irregular consistency as the gap between each of the average value is large. The average value at point 2 is the lowest as compared to the other points. The error bars show long dimension, which means that the concentration of calculated average values is low.

Total Average A & B

Total average at positions A & B

The total average values are gradually decreasing across all of three points, which indicates the presence of irregular consistency. The error bar appears to be small that means the total average values of surface irregularities on the sample are slightly certain.

Table 10 Analysis of vertical results for 80% of filler

Vertical results	Analysis
Sample A at Point 1 	<i>Position A</i> Through the graph, the data can be seen gradually increases across all of the readings with small gap between each readings.
Sample A at Point 2 	The surface roughness values from Reading 2 and Reading 3 produce consistent graph plot while the value at Reading1 is the highest at this point.
Sample A at Point 3 	The graph exhibits consistency between all of the values of surface roughness across all of the readings.
Average Sample A 	Ra is gradually decreasing across all of three points, which indicates the presence of irregular consistency. The error bar appears to be large it is caused by the low concentration of calculated average values plus the difference between the highest and the lowest average value is high, 2.13 µm.
Sample B at Point 1 	<i>Position B</i> At Reading 1 and Reading 2, the data shows consistency but the data increases from Reading 3, which shows obvious gap between the values from Reading 2 and Reading 3.

Sample B at Point 2

From the graph, the surface roughness value at Reading 1 is the highest and the values gradually decrease across all of the readings with small difference.

Sample B at Point 3

The surface roughness value at Reading 3 is the highest as compared to other two points that have small difference in value between each other.

Average Sample B

The graph displays irregular consistency as the difference between each of the value is large. The average value at point 3 is the lowest as compared to the other points. The error bar appears to be short that means the average values surface irregularities on the sample are slightly certain.

Total Average A & B**Total average at positions A & B**

The total average values are gradually decreasing across the points with the range of gap 0.8–1.3 μm. The error bar appears to be large that means the total average values of surface irregularities is uncertain.

Table 11 Analysis of vertical results for 90% of filler

Vertical Results	Analysis
Sample A at Point 1 	<i>Position A</i> The surface roughness values from Reading 1 and Reading 3 are consistent while the value at Reading 2 is a bit decreasing.
Sample A at Point 2 	Graph shows that the surface roughness values from Reading 2 and Reading 3 are consistent while the value at Reading 1 has obvious difference from the other values.
Sample A at Point 3 	From the graph, the surface roughness value at Reading 1 is the highest while the values from Reading 2 and Reading 3 display stable consistency.
Average Sample A 	Each of average values has small difference between all of the points and the average value at point 2 being the highest value. The error bar appears to be small that means the surface irregularities on the sample are slightly consistent.
Sample B at Point 1 	<i>Position B</i> The total Ra values from Reading 1 and Reading 3 exhibit consistency while the value at Reading 2 is the lowest among them.

Sample B at Point 2

From the graph, the surface roughness values from Reading 3 shows the highest value of surface roughness while at Reading 1 and Reading 2, their values are consistent

Sample B at Point 3

The Ra values from Reading 1 and Reading 2 are consistent while at Reading 3 shows the highest value of surface roughness.

Average Sample B

The average values at point 1 and point 2 show consistency while the average values at point 3 being the highest among all of the points. The error bar appears to be small that means the surface irregularities of the sample are slightly certain.

Total Average A & B

Total average at positions A & B

From the graph, it shows that the total Ra values at each point have small difference between each other. The error bar can hardly be seen, which explains that there is slightly small difference between the total average values and the concentration of calculated average values is high.

Surface Roughness in Horizontal Direction

Each of the data is translated into the graph that represents three types of relation; relationship between surface roughness and number of measurement taken on the same spot, relationship between Ra and point of measurement and relationship between

Table 12 Horizontal direction results

Table 13 Analysis of horizontal results for 10% of filler

Horizontal Results	Analysis
Sample A at Point 1 	<i>Position A</i> Graph has low surface roughness that is in the range of 0.18–0.25 μm, which means that the result has stable consistency.
Sample A at Point 2 	The graph illustrates low surface roughness where the range is 0.18–0.25 μm, similarly to the previous point.
Sample A at Point 3 	This area has the lowest surface roughness that is in range of 0–0.15 μm, which means that it has the smoothest surface.
Average Sample A 	At point 3, Ra between three points is the lowest as compared to the other two points, but the sample still has smooth surface. The error bar appears to be short since the difference between the highest and the lowest values at each point are 0.021 μm, 0.042 μm and 0.010 μm.
Sample B at Point 1 	<i>Position B</i> The graph illustrates low surface roughness with small gap of value between the times of data reading.

Sample B at Point 2

Graph has the highest surface roughness value as compared to other points in both positions, but in consistent range.

Sample B at Point 3

Graph has the lowest surface roughness value as compared to the value in this position. At third reading when the data is taken, the value slightly decreases.

Average Sample B

At the first and second points the data is taken, the Ra value is consistent while at the third point, the value decreases, but the sample is still in homogenous solution since the gap value is small. The error bar can barely be seen since the difference between the highest and the lowest values at each point is not exceeding 0.03 μm.

Total Average A & B

Total average at positions A & B

At point 1 and 2, the total Ra is consistent while at point 3, it decreases in value but in small gap, which describes that the sample is in homogenous solution. The error bar can barely be seen, which proves that the total average values are more certain.

Table 14 Analysis of horizontal results for 20% of filler

Horizontal Results	Analysis
Sample A at Point 1  Surface Roughness (μm) 1 2 3	<i>Position A</i> This area has the lowest surface roughness that is in range of 0.5–1 μm, which means that it has the smoothest surface.
Sample A at Point 2  Surface Roughness (μm) 1 2 3	Graph consists of range of surface roughness around 1.45 μm with consistent gap, which is the highest in this position. Ra value rapidly increases as compared to the previous point.
Sample A at Point 3  Surface Roughness (μm) 1 2 3	This area has lower surface roughness as compared to the data at Point 2 with small gap between each data that proves the result has stable consistency.
Average Sample A  Surface Roughness (μm) 1 2 3	At point 1, the Ra between three points is the lowest as compared to the other two points, but the sample still has smooth surface. The error bar can barely be seen that means the surface irregularities on the sample are slightly consistent.
Sample B at Point 1  Surface Roughness (μm) 1 2 3	<i>Position B</i> It has the lowest surface roughness value as compared to the value in this position with small gap of value between the times of data reading.

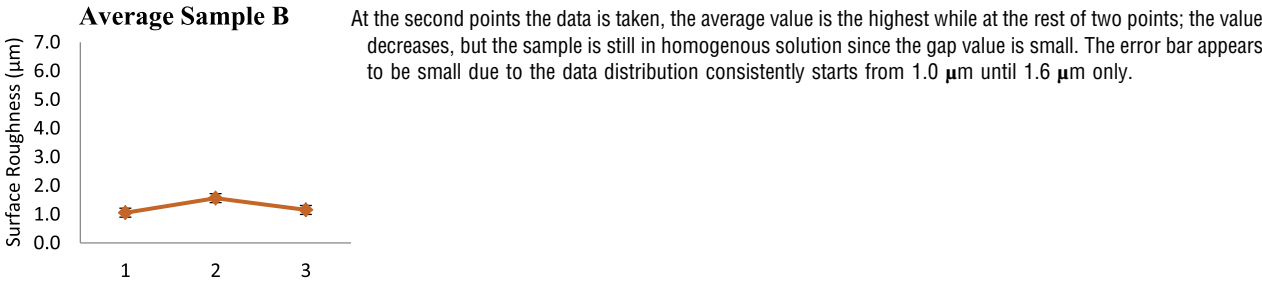

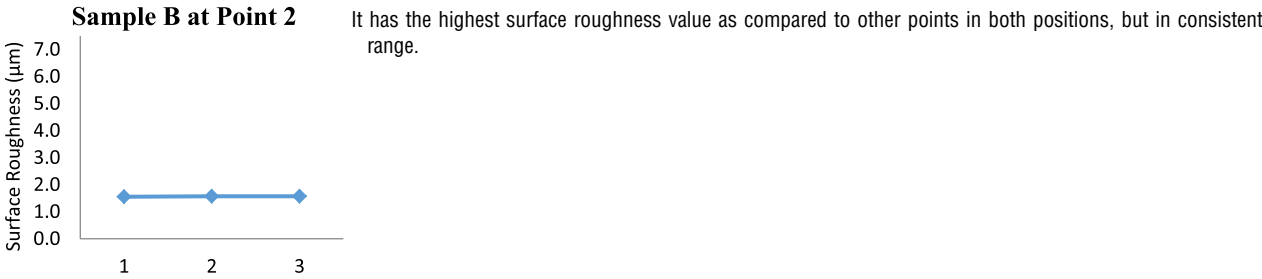

Table 15 Analysis of horizontal results for 30% of filler

Horizontal Results	Analysis
Sample A at Point 1 	<i>Position A</i> It has surface roughness that is in range of 1.28–1.35 μm, which means that the result has stable consistency as it has small gap between the data.
Sample A at Point 2 	The graph illustrates low surface roughness where the range is 1.5–1.6 μm, but it increases as compared to the previous point.
Sample A at Point 3 	This area has the lowest surface roughness that is in the range of 1.13–1.16 μm, which means that it still has the smoothest surface.
Average Sample A 	At point 3, the average of surface roughness between three points is the lowest as compared to the other two points, but the sample still has smooth surface. The error bar appears to be small due to the data distribution consistently starts in the range of 1.13 μm until 1.61 μm.
Sample B at Point 1 	<i>Position B</i> It has the lowest surface roughness value as compared to other points in both positions, but in consistent range.

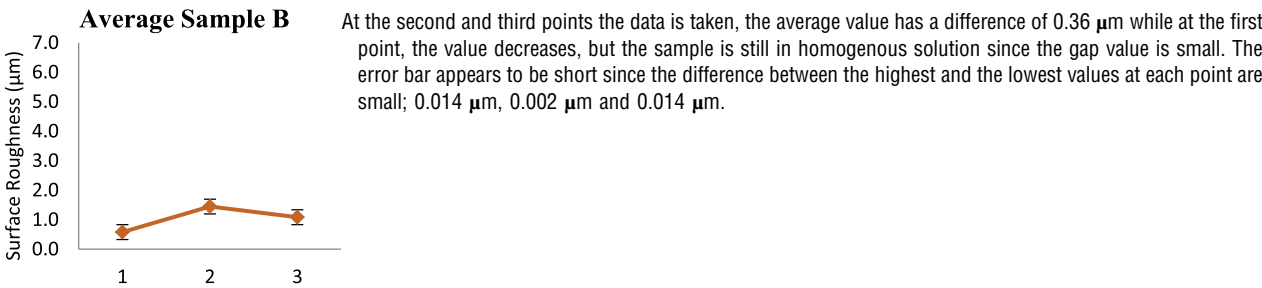

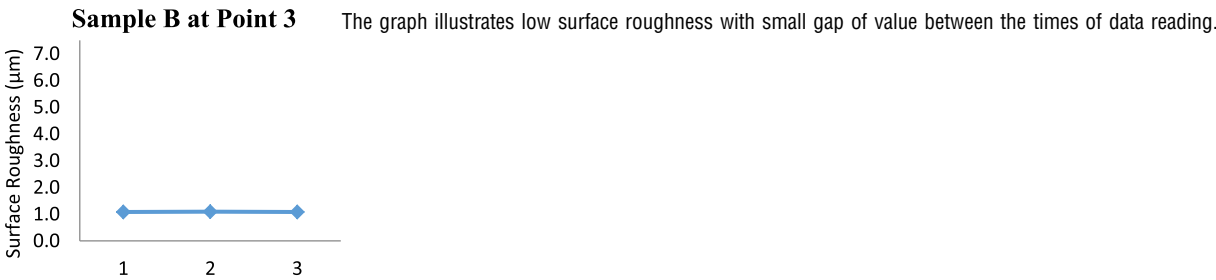

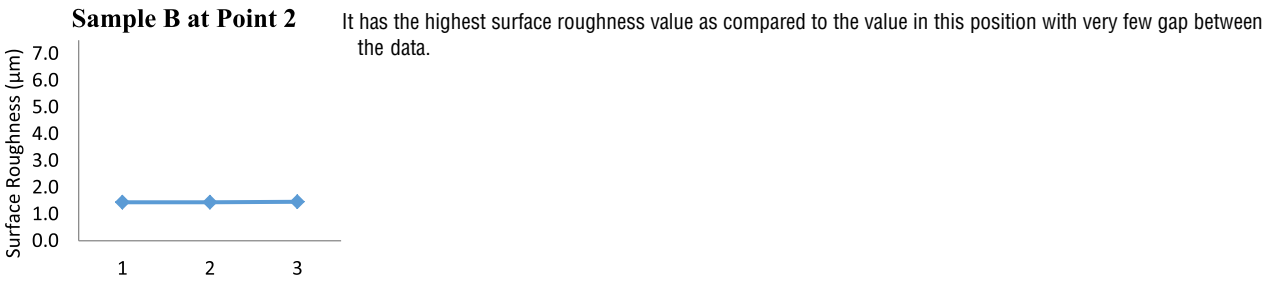

Table 16 Analysis of horizontal results for 40% of filler

Horizontal Results	Analysis
Sample A at Point 1  Surface Roughness (μm) 1 2 3	<i>Position A</i> The value of surface roughness at this point is the highest for 40% of filler, which ranges up to 0.5 μm.
Sample A at Point 2  Surface Roughness (μm) 1 2 3	The graph exhibits there is small increasing of value at Reading 3 as compared to two other remaining readings.
Sample A at Point 3  Surface Roughness (μm) 1 2 3	The data presents up to no difference among all of the three readings since their values are around 0.3 μm.
Average Sample A  Surface Roughness (μm) 1 2 3	The average value of surface roughness is the highest at point 1 but the average value starts to decrease at point 2 and point 3. The error bar can hardly be seen, which proves that there is small difference between the average values.
Sample B at Point 1  Surface Roughness (μm) 1 2 3	<i>Position B</i> Highest surface roughness with small gap of value between the times of data reading.

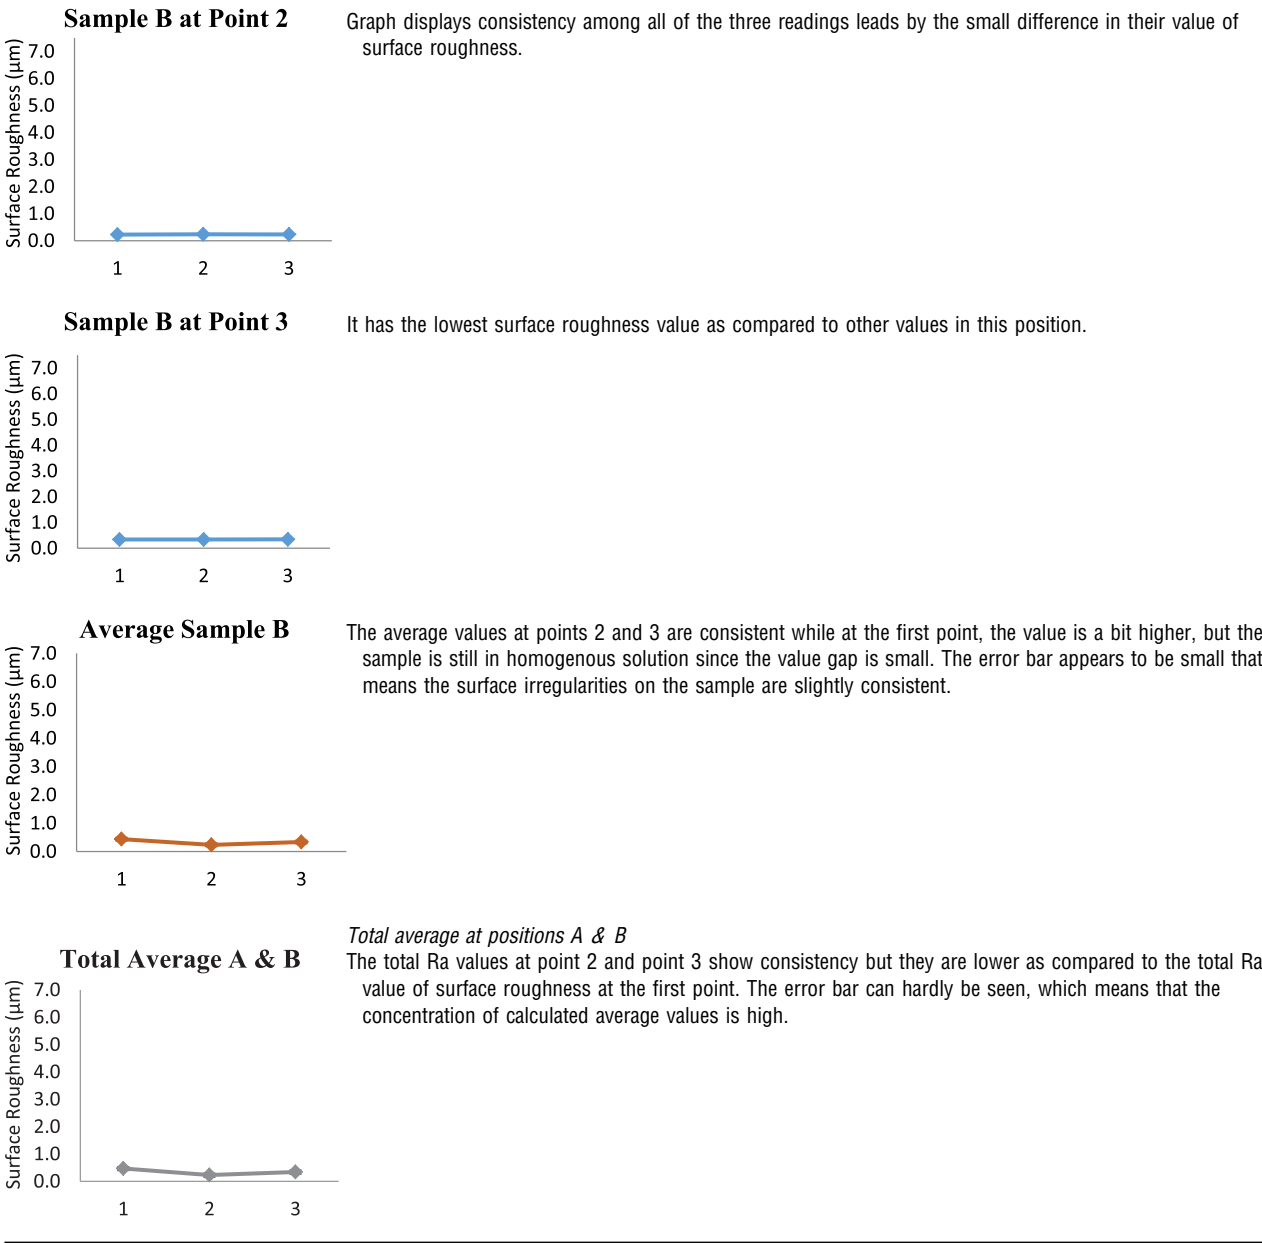

Table 17 Analysis of horizontal results for 50% of filler

Horizontal Results	Analysis
Sample A at Point 1  Surface Roughness (μm) 1 2 3	<i>Position A</i> The graph shows a stable consistency among the values since the difference of surface roughness show no difference.
Sample A at Point 2  Surface Roughness (μm) 1 2 3	The graph also encounters similar situation as in the previous graph where the data being displayed has small difference.
Sample A at Point 3  Surface Roughness (μm) 1 2 3	The values from Reading 1 and Reading 2 are consistent but at Reading 3, the value is slightly increasing.
Average Sample A  Surface Roughness (μm) 1 2 3	From Point 3, the increasing average value is obvious while the average values at Point 1 and Point 2 are consistent. The error bar appears to be obvious as the difference between the highest and the lowest values at each point are small; 0.019 μm, 0.015 μm and 0.015 μm.
Sample B at Point 1  Surface Roughness (μm) 1 2 3	<i>Position B</i> From the graph, the surface roughness value at Reading 1 is the highest while the values from Reading 2 and Reading 3 display stable consistency.

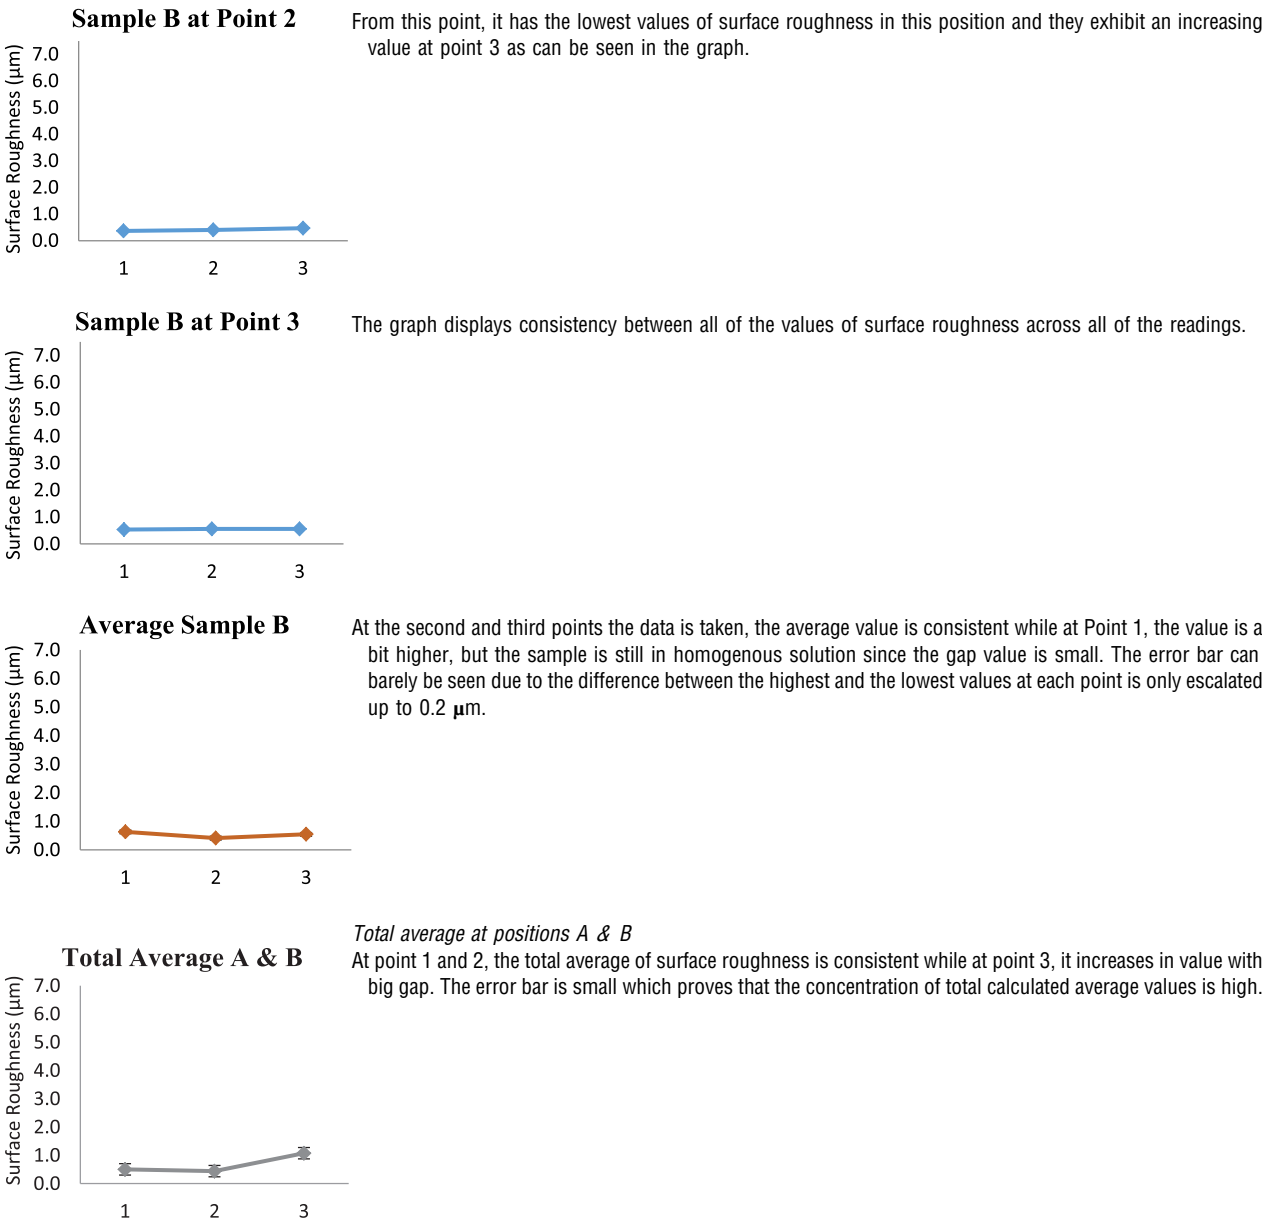

Table 18 Analysis of horizontal results for 60% of filler

Horizontal Results	Analysis
Sample A at Point 1  Surface Roughness (μm) 1 2 3	<i>Position A</i> The values rapidly increasing from the previous percentage of fillers where they start from 2 μm and above.
Sample A at Point 2  Surface Roughness (μm) 1 2 3	The graph displays stable consistency since their range is consistent that is around 3.2 μm.
Sample A at Point 3  Surface Roughness (μm) 1 2 3	The value from Reading 1 is a bit higher as compared to the values from Reading 2 and Reading 3 that are consistent between each other.
Average Sample A  Surface Roughness (μm) 1 2 3	There is no stable consistency among the average values being displayed in the graph as the difference value between the highest and the lowest data is 1.411 μm. The error bar is in obvious dimension since the difference between the highest and the lowest values at each point are 0.127 μm, 0.019 μm and 0.127 μm
Sample B at Point 1  Surface Roughness (μm) 1 2 3	<i>Position B</i> The graph exhibits consistency in the data but the value from Reading 3 is slightly lower than the other values.

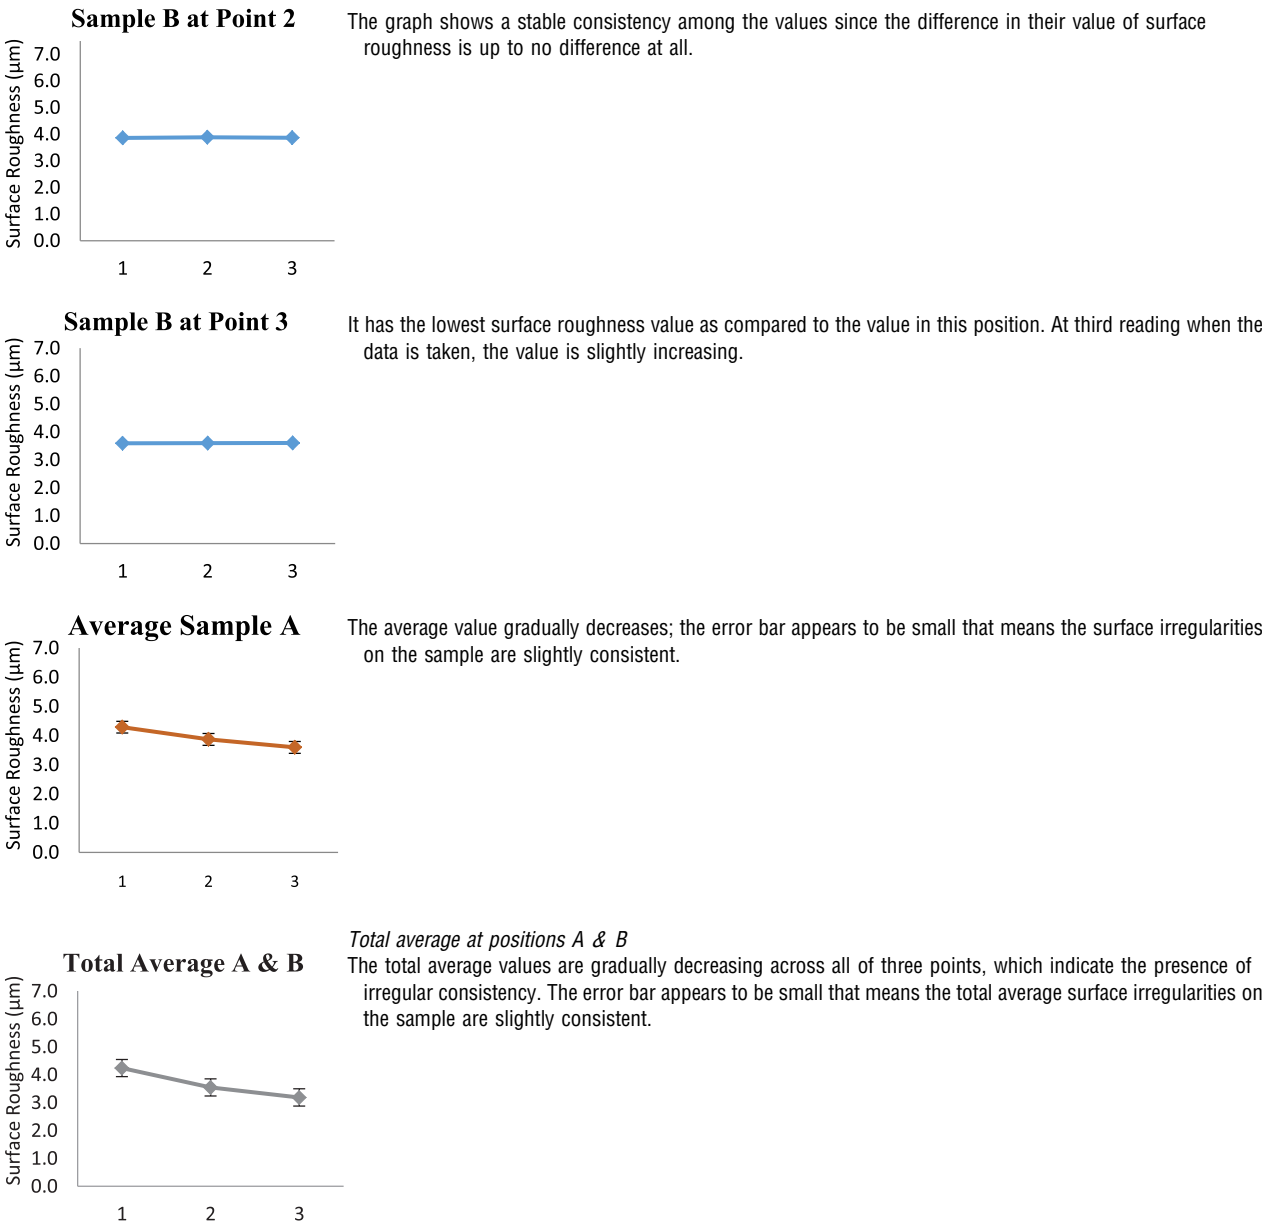

Table 19 Analysis of horizontal results for 70% of filler

Horizontal Results	Analysis
Sample A at Point 1 	<i>Position A</i> From the graph, it shows that the values are consistent as all of the values start from 3.5 μm.
Sample A at Point 2 	Data distribution does not produce obvious inconsistency in the graph as the gap between each data is small.
Sample A at Point 3 	The data produces a consistent graph plot since there is small gap between all of the surface roughness values.
Average Sample A 	The graph displays irregular consistency as the difference between each of the average values is large. The average value at point 1 is the lowest as compared to the other points. The error bar appears to be small, which is caused by the concentration of calculated Ra values is high. The difference between the highest and the lowest average values is low, 0.954 μm.
Sample B at Point 1 	<i>Position B</i> It has the lowest surface roughness value as compared to the value in this position. At third reading when the data is taken, the value slightly increases.

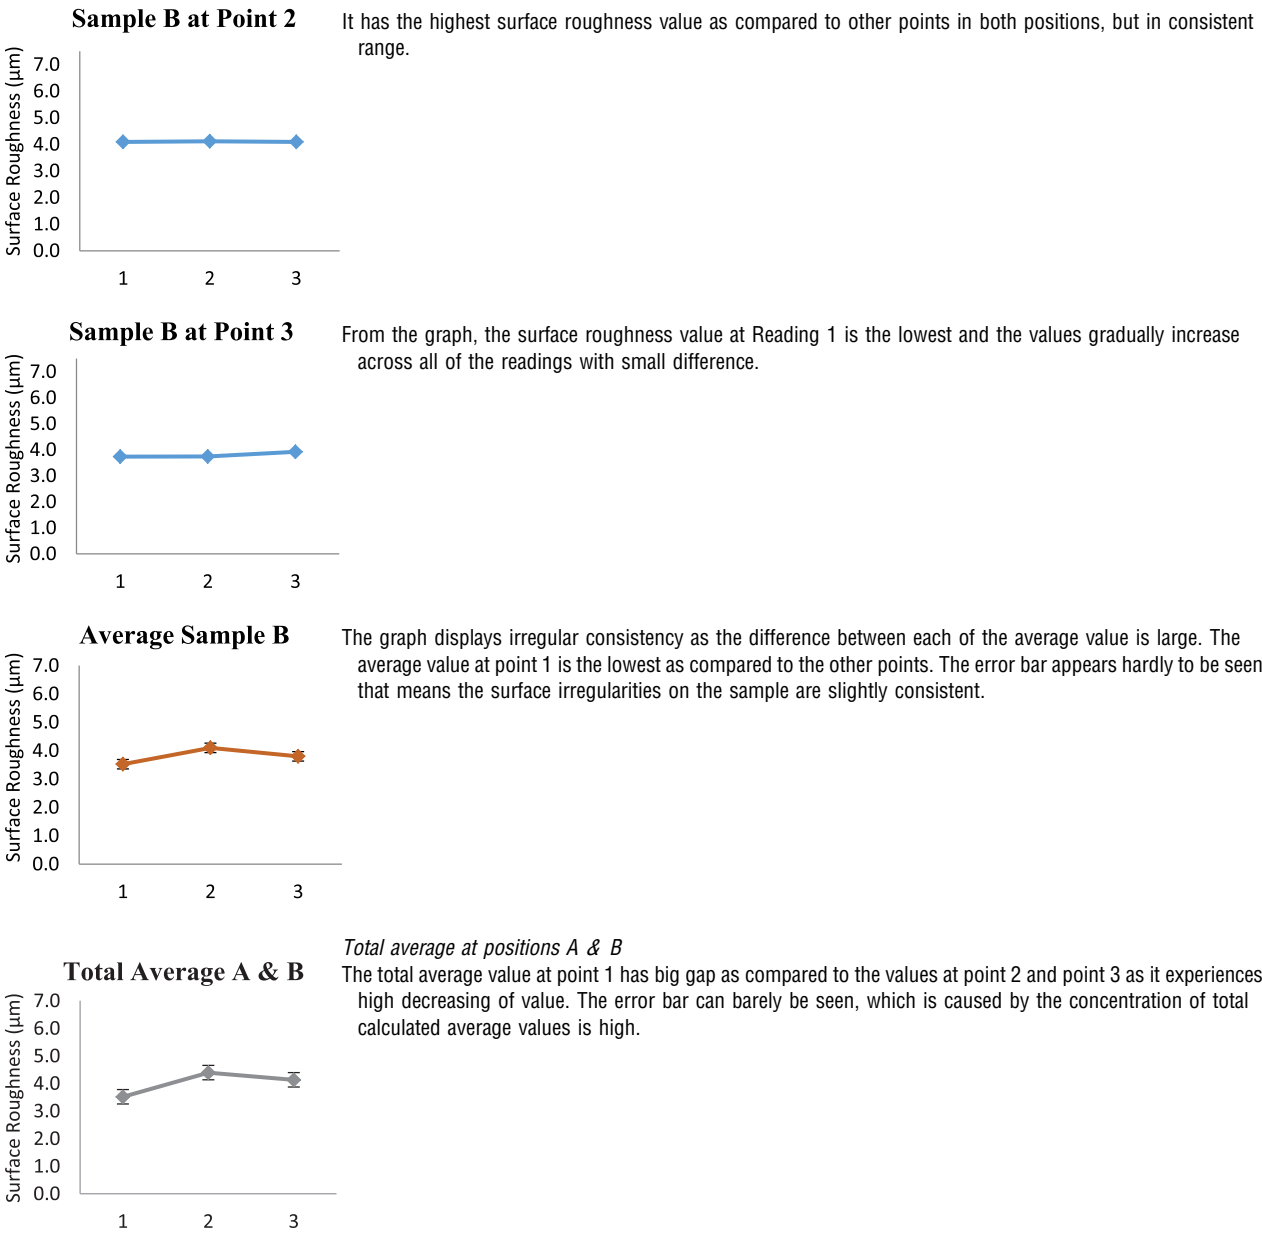

Table 20 Analysis of horizontal results for 80% of filler

Horizontal Results	Analysis
Sample A at Point 1 	<i>Position A</i> The values from Reading 1 and Reading 2 are consistent but at Reading 3, the value is slightly increasing.
Sample A at Point 2 	It has the lowest surface roughness value as compared to the value in this position. At second reading when the data is taken, the value slightly increases.
Sample A at Point 3 	The graph shows stable consistency since their range is consistent that is around 3.8 μm.
Average Sample A 	The graph exhibits irregular consistency as the gap between each of the average value is large. The average value at point 2 is the lowest as compared to the other points. The error bar appears to be large, which is caused by the concentration of calculated average values is low. The difference between the highest and the lowest average values is high, 2.072 μm.
Sample B at Point 1 	<i>Position B</i> The surface roughness values from Reading 1 and Reading 3 have small difference while the value from the second reading is the lowest for this point.

Sample B at Point 2

The data produces a consistent graph plot since there is small gap between all of the surface roughness values.

**Sample B at Point 3**

The graph shows a stable consistency among the values since the difference in their value of surface roughness is up to no difference.

**Average Sample A**

The average value gradually increases; the error bar appears barely to be seen that means the surface irregularities on the sample are certain.

**Total Average A & B**

Total average at positions A & B

From the graph; at point 2 and 3, the total average value has small difference while at point 1; it has the highest value but in small gap. The error bar appears to be small since the difference between the highest and the lowest total average values is below 1 μm.

Table 21 Analysis of horizontal results for 90% of filler

Horizontal Results	Analysis
Sample A at Point 1 	<i>Position A</i> The surface roughness values from Reading 1 and Reading 2 produce consistent graph plot while the value at Reading 3 is slightly lower at this point.
Sample A at Point 2 	The values rapidly increasing from the previous percentage of fillers where they start from 5 µm and above. From the graph, the values at Reading 2 and Reading 3 are consistent while at Reading 1, the value is a bit lower.
Sample A at Point 3 	The value from Reading 3 is the lowest as compared to the values from Reading 1 and Reading 3 that have small gap between each other.
Average Sample A 	Through the graph, Ra starts to increase from Reading 1 to Reading 2 with the difference value of 0.882 µm while the data keeps consistent between the second and third readings. The error bar is in small dimension that is caused by the difference between the highest and the lowest values at each point is only up to 0.25 µm.
Sample B at Point 1 	<i>Position B</i> The graph displays consistency between all of the values of surface roughness across all of the readings with slight increase at Reading 3.

From the graph, it shows that the values are consistent as all of the values start from 5.4 μm .

It has the highest surface roughness value for 90% of filler and the value keeps in stable consistency as their values start from 6.2 μm and above.

Average values from points 1 and 2 have small difference but the average value at point 3 increases thus, being the highest value. The error bar appears to be short due to the difference between the highest and the lowest values at each point is only escalated up to 0.042 μm .

Total average at positions A & B

Total Ra value keeps increasing across the three points as shown in the graph. The error bar appears to be small that means the total average values of surface irregularities on the sample are certain and the concentration of calculated average values is high.

total Ra and measurement points at both positions. The overall results for horizontal is shown in [Table 12](#). In addition, [Table 13](#) shows the results for 10% filler, [Table 14](#) for 20% filler, [Table 15](#) for 30% filler, [Table 16](#) for 40% filler, [Table 17](#) for 50% filler, [Table 18](#) for 60% filler, [Table 19](#) for 70% filler, [Table 20](#) for 80% filler and [Table 21](#) for 90% filler, respectively.

From the table of results in both directions, the values of surface roughness for the sample of 10% of filler until 50% of filler are below 1.9 μm with the lowest value of Ra in vertical direction is 0.091 μm while in horizontal direction is 0.115 μm . The highest value of Ra from 10% of filler until 50% of filler in vertical direction is 1.803 μm and for the horizontal direction is 1.606 μm .

For 60% and the rests of the sample, their values of surface roughness in both directions surpass 2.0 μm with the highest value of Ra is 7.017 μm in vertical direction and 6.276 μm in horizontal direction.

In vertical direction, graphs that show stable consistency are resulted from 10% of filler up to 50% of filler including 90% of filler. The graph with the most stable consistency is exhibited by the 50% of filler since there is not much difference between the taken data. The rests of the sample from 60% to 80% of filler display irregular consistency among the recorded data. Large error is detected in the graphs that indicating the concentration of calculated average values is low, thus the average value is uncertain.

For horizontal direction, graphs that illustrate the stable consistency are contributed from 10% to 70% of filler including 90% of filler. The error bar from the graphs of average values and total values of Ra are small or can barely be seen, which prove that the concentration of calculated average values is high. Thus, the average value is certain. Graph of average and total average values of

Ra at 80% of filler display the most obvious difference in the error bar as the error bar is long. It means that the surface irregularities on the sample are not consistent.

From all of the graphs that had been constructed, they attribute that the samples with lower filler percentage have consistent Ra and smooth surface. Meanwhile, for the samples with high percentage of filler have inconsistent surface irregularities that contribute to rougher surface.

Conclusion

Through the formulation of ink that has been done before, all of the processes including mixing, printing and curing can be performed to fabricate the ink on the substrates in house. After the fabrication has been carried out, the behaviour of conductive ink is investigated through various tests and one of them is surface roughness. Based on the results, it can be concluded that if the surface texture is the highlight of the subject, it can be summarized from the results of average value of surface roughness. They show that the samples with lower filler percentage have consistent average value and smooth surface. Meanwhile, for the samples with high percentage of filler have inconsistent surface irregularities that contribute to rougher surface.

Introduction

After two decades of research and development, the additive manufacturing (AM) industry has started to grow with new methods, technologies, and applications (Wohlers, 2007). In addition to the different AM techniques, preparation of filament materials for AM is also gaining great attention from researchers. Many methods are being used in today's industry for the preparation of filament (such as screw extrusion, direct extrusion, drawing, etc.). Most researchers have a significant inclination toward using screw extrusion for preparation of filament for AM because the single-screw extruder has wide applications in the polymer processing industry (Campbell *et al.*, 2001). However, single-screw and twin-screw extrusion are available for material processing (Campbell and Spalding, 2013). Some researchers have used hemp fiber in HDPE to improve mechanical properties. Also, some studies have reported the use of carbon fiber (CF), glass fibers, wood flour, sand, natural fibers, aluminum powder, aluminum oxide, and carbon nanotubes as reinforcements (Herrera-Franco *et al.*, 1997; Adhikary *et al.*, 2008; Lu and Oza, 2013; Jen and Huang, 2014; Oliveux *et al.*, 2015; Yildirim *et al.*, 2015) to improve properties.

Furthermore, fused deposition modeling (FDM) was used in some studies to create specific dimensions for wear testing (Singh and Singh, 2016). As reported in this study, initially ABS was used as filament wire in the FDM machine. However, ABS has its own disadvantage in terms of strength and hardness (Zhong *et al.*, 2001), which were improved by reinforcement in the ABS matrix. In the present work, an effort has been made to develop an alternate filament for FDM with hybrid reinforcement of SiC and Al₂O₃ with Nylon-6 as matrix material to improve the mechanical properties of alternate filament wire.

Screw Extrusion

Extrusion methods are widely used for processing polymers and composites containing them, agricultural raw materials, food, waste, meat, and leather, as well as other raw materials (Mikulionok and Radchenko, 2012). Single-screw and twin-screw extruders are available for recycling processed materials. However, both have different process parameters. Single-screw and twin-screw extruders have some differences and benefits depending on the plastic being processed (Rosato and Knovel (Firm), 1998). In polymer processing technology, screw extrusion is the most important operation (Covas and Gaspar-Cunha, 2001).

Plastic extrusion is a process in which plastic/polymer material is melted and extruded through a die to create a desired shape. Most commonly, plastic extruded materials are formed into a cylindrical shape. To maintain the uniformity of extruded material, some arrangements are made to preheat the material (Al-Salem *et al.*, 2010). Cooling time and rolling speed of the material plays a major role in dimensional accuracy and properties of the wire being extruded (Wang *et al.*, 2011). Most of the plastic materials are available in the form of powder or granules. These are processed at room temperature. The plastic extrusion machine melts the material and homogenizes it before it enters the die. Conversion from a cold state to a hot state accounts for some energy. The surface profile depends on the cross-sectional shape, surface angle, and layer thickness (Ahn *et al.*, 2009). The ratio of the channel depth in the feed section to the channel depth in the metering section is often referred to as the compression ratio of the screw. Pumping action is basically forced flow of melted plastic from hopper end to die end. It is only effective if feeding volume is more than volume coming out from die front or die outlet. Because compression tries to decrease the volume. Further volume ratio and compression ratio both are same (Campbell and Spalding, 2013).

The extruder has the following parts:

- Hopper.
- Cylindrical barrel.
- Screw.
- Die head.
- Motor (for running of the screw).

The material enters the barrel through the hopper via gravity. The cylindrical barrel is surrounded by heaters that can be controlled manually with a set of specific temperature ranges. Generally, the temperature range of a normal screw extruder is up to 275°C, which is enough to melt thermoplastic materials. As material enters the barrel, the material starts heating up. The screw starts leading the material in the forward direction toward the die. The length of the barrel plays a major role. The role of screw speed is also important. If the screw has more speed, then the material will not melt properly, because the material will lead at a faster speed. If the speed of the screw is low, then the material will be overly melted and the wire will not form properly.

Fig. 1 Schematic of a single-screw extruder (Covas and Gaspar-Cunha, 2001).

The screw pushes the material into the barrel and leads it to the die. There can be multiple heating zones. Those heating zones gradually increase the temperature of the material. The pressure, which the screw is exerting on the material, may reach to 5000 psi (34 MPa). Then, material reaches the breaker plate, which creates back pressure. This is required for uniform mixing and uniform melting of material. After passing through the breaker plate, material arrives at the die, starts passing through it, and wire is formed. **Fig. 1** shows the basic schematic of single-screw extruder.

Screw extruders are capable of expelling material through a die under high pressure. The screw inside the barrel continuously exerts pressure on the material being processed inside. Some researchers have worked on reinforcements for different materials in polymer material. After processing the material in a single-screw extruder machine, wires are formed and then fed into the FDM commercial setup to make cylindrical pins.

FDM

One of the most common rapid prototyping (RP)/AM processes is FDM (Espalin *et al.*, 2014). Rapid prototypes can be of invaluable help in testing esthetic, functional, and engineering performance of a product during its development cycle. In principle, any physical model should reproduce all relevant product properties at an accuracy level consistent with the intended evaluation stage (Armillotta, 2006). Rapid manufacturing is one of the manufacturing technologies used for fabrication of three-dimensional (3D) models using the layered manufacturing (LM) process by stacking and bonding thin layers (Ahn *et al.*, 2009). LM processes are often used in various fields such as medical sciences, jewelry, construction industry, automobile industry, aircraft industry, and others (Chua *et al.*, 2003; Gebhardt and Gibson, 2003/2006; Venuvinod and Ma, 2004). Creative production techniques have the advantage of manufacturing products by AM without the need for forming tool (Bagsik and Schöppner, 2011). It is also important to highlight that the wrong choice of process parameters may result in a lack of adherence between layers and even to the platform, resulting in warping of the object and faulty formation of layers (Cunico, 2013).

As a consequence of the process characteristics, negative surfaces are generally produced by the deposition of a support material that is removed at the end of the manufacturing stage. This stage is called the postprocessing stage (Volpato, 2007; Gibson *et al.*, 2010). It is important to note that even though in some cases the support material is water-soluble, the cost of the material is extremely high, making the process more expensive (Cunico, 2013). Commercially available RP methods include the following: stereo-lithography, selective laser sintering, FDM, laminated object manufacturing, ballistic particle manufacturing, and 3D printing (Pham and Gault, 1998). Among these, FDM is the most preferred and simple method for RP. **Fig. 2** shows the schematic of the FDM process.

In FDM, a feed stock filament wire is used, and usually that wire comprises acrylonitrile butadiene styrene (ABS). ABS has some specific properties, such as tensile strength, Young's modulus, and percentage elongation. Many researchers have worked on parametric optimization of FDM with ABS as a filament (Panda, 2009). In this study, FDM from Stratasys USA was used. This machine can only run ABS wire with a melt flow index (MFI) of 2.41 g/10 min.

A pilot experimentation has been performed to find MFI values by selecting different proportions of SiC and Al₂O₃ in the Nylon-6 matrix.

Case Study of Polymer Single-Screw Extrusion

To study the effect of reinforcement particle size and to compare the properties of the obtained filament with single and hybrid reinforcements, two case studies are discussed here.

Case Study 1

In case study 1, an alternative FDM filament wire was fabricated through the extrusion process. For filament development, Al₂O₃ powder (supplied by Thomus Bakers) and Nylon-6 granules were used as reinforcement and polymer matrix, respectively. Three

Fig. 2 Schematic of the FDM extrusion and deposition process (Zein *et al.*, 2002).

different sizes of Al_2O_3 powder (SPS, DPS, and TPS) were used to study the effect of the reinforcement particle size on desirable characteristics of filament and its resulting parts. Because the aim of the present study was to replace the commercial filament (ABSP-430) with an alternative prepared filament, to have a successful run in FDM, the rheological property of the alternative filament proportion was matched with ABSP-430 (2.41 g/10 min). MFI, one of the prominent rheological tests (Garg and Singh, 2015), was performed for various combinations of Nylon-6 and Al_2O_3 powder, as shown in Table 1. The test was performed using the melt flow index (pictorial view given in Fig. 3) as per the ASTM-D1238 standard (ie, at a temperature of 230°C and a force of 3.8 kg).

Although Table 1 indicates that none of the combinations obtained similar MFI values, the filament wires prepared could be used for open-source FDM systems. Therefore, some of the proportions were selected for filament development on a single-screw extruder at fixed processing parameters (mentioned in Table 2). Table 3 shows the various output parameters for this study.

Testing for mechanical properties

Table 4 summarizes the average of three runs for various mechanical properties (such as percentage elongation, tensile strength, yield strength, and Young's modulus) of selected compositions (as per Table 1) as tested on a universal tensile tester (UTM). The tensile properties of feed stock filament wires were tested as per the ASTM-638 standard. The mechanical properties tested are rate-dependent and were tested at strain rate of 50 mm/min.

Design Expert software was used to analyze the results for fabricated filaments. It offers comparative tests, screening, characterization, optimization, robust parameter design, mixture designs, and combined designs, and it provides test matrices for screening up to 50 factors. Statistical significance of these factors is established with analysis of variance (ANOVA). Graphical tools help to identify the impact of each factor on the desired outcomes and reveal abnormalities in the data. Based on Table 4, and by applying the mixture design (user-defined model with four components and four responses), ANOVA for the mixed quadratic model was performed (see Table 5).

The F-value of 8.47 implies that the model is significant. There is only a 1.41% chance that the F-value this large could occur due to noise. Values of Prob>F less than 0.0500 indicate that the model terms are significant. In this case, linear mixture components AC and BC are significant model terms. Values greater than 0.1000 indicate that the model terms are not significant. If there are many insignificant model terms (not counting those required to support hierarchy), then model reduction may improve the model. The R-values along with mean and standard deviation values are provided in Table 6.

After excluding a one-outlier value from the model in Design Expert, various R-squared values were obtained (Table 7). The R-squared value is a statistical measure of how close the data are to the fitted regression line. It is also known as the coefficient of determination. According to Table 6, it was 0.9824, which is a satisfactory value and signifies that the developed statistical model yielded a good fit.

The adjusted R-squared value compares the explanatory power of regression models that contain different numbers of predictors. It increases only if the new term improves the model more than would be expected by chance. It decreases when a predictor improves the model by less than expected by chance. The adjusted R-squared can be negative, but it is usually not. It is always lower than the R-squared value. In the present study, in Table 6, it is 0.9718, which is less than the R-squared value.

The predicted R-squared value indicates how well a regression model predicts responses for new observations. If the predicted R-squared is much lower than the regular R-squared, then there is a chance that the model contains too many terms. In the present study (as per Table 6), it is 0.9381, which is in reasonable agreement with the adjusted R-squared value.

Predicted R-squared	0.9381
Adequate precision	24.910

Table 7 Standard error for components

Component	Coefficient estimate	DF	Standard error	95% CI, low	95% CI, high
Nylon-6	–14.30	1	7.35	–32.29	3.69
Al ₂ O ₃ 150 μm	1.73	1	3.32	–6.38	9.85
Al ₂ O ₃ 120 μm	16.21	1	1.87	11.62	20.79
Al ₂ O ₃ 100 μm	9.88	1	3.33	1.72	18.03

Adequate precision measures the signal-to-noise ratio. A ratio greater than 4 is desirable. A ratio of 24.910 indicates an adequate signal. This model can be used to navigate the design space. The values of different model components and the values of their standard errors are listed in [Table 7](#).

After analyzing the results for various mechanical properties, a linear model was developed to predict the earliest outputs. [Eq. 1](#) shows the model for percentage elongation of the filament wire:

$$\text{Percentage elongation} = | -14.29722 \times a + 17.76623 \times b + 46.71259 \times c + 34.04853 \times d | \quad (1)$$

Where, a, b, c, and d represent %wt of Nylon-6, Al_2O_3 (150 μm), Al_2O_3 (120 μm), and Al_2O_3 (100 μm), respectively.

To validate and check the adequacy of the model, a corollary was performed as per the experiment 10 in [Table 4](#). [Eq. \(2\)](#) shows the predicted value of percentage elongation:

$$\begin{aligned} \text{Percentage elongation} &= | -14.29722 \times 0.6 + 17.76623 \times 0.1334 + 46.71259 \times 0.1333 + 34.04853 \times (0.1333) | \\ &= 4.55(\text{predicted value}) \end{aligned} \quad (2)$$

The predicted value was compared with the experimental value, and it was found that the percentage of error is less than 3%; therefore, it can be concluded that the model developed is adequate to predict the response in terms of percentage elongation.

Similarly, the mathematical model for tensile strength was developed and provided [Eq. \(3\)](#).

$$\text{Tensile strength} = | 0.60983 \times a + 8.24141 \times b + 5.33765 \times c + 1.95317 \times d | \quad (3)$$

To validate the model, a corollary was performed in a similar way (see [Eq. \(4\)](#)).

$$\begin{aligned} \text{Tensile strength} &= | 0.60983 \times 0.6 + 8.24141 \times 0.1334 + 5.33765 \times 0.1333 + 1.95317 \times 0.1333 | \\ &= 2.24(\text{predicted value}) \end{aligned} \quad (4)$$

The predicted value was compared with the experimental value. The percentage error was checked and was less than 4%.

Further, a mathematical model for yield strength was developed (see [Eq. \(5\)](#)) and validated by performing a corollary (provided in [Eq. \(6\)](#)).

$$\text{Yield strength} = | 2.66776 \times a - 0.74963 \times b - 1.41875 \times c + 2.78802 \times d | \quad (5)$$

Similarly, [Eq. \(6\)](#) shows results for the corollary that was performed.

$$\begin{aligned} \text{Yield strength} &= | 2.66776(0.6) - 0.74963(0.1334) - 1.41875(0.1333) + 2.78802(0.1333) | \\ &= 1.55 \text{ (predicted)} \end{aligned} \quad (6)$$

After performing the corollary, the percentage error was found to have very low predicted and experimental values.

Similarly, a mathematical model for Young's modulus was developed (see [Eq. \(7\)](#)).

$$\text{Young's modulus} = | -4.44512 \times a + 220.15468 \times b + 144.26259 \times c - 22.85559 \times d | \quad (7)$$

After obtaining the mathematical model, it was cross-checked for validation. [Eq. \(8\)](#) shows the corollary performed to validate that model.

$$\begin{aligned} \text{Young's modulus} &= | -4.44512 \times 0.6 + 220.15468 \times 0.1334 + 144.26259 \times 0.1333 - 22.85559 \times 0.1333 | \\ &= 42.88 \text{ (predicted)} \end{aligned} \quad (8)$$

After performing the corollary, the percentage error was found to be less than 0.67%.

Wear testing

After testing sample wires on a UTM, filament wire was prepared on a screw extruder by using the same compositions that were selected previously. Then, those wires were made to run on the FDM machine, and pins of specific dimensions (as per ASTM standard) were made to test the wear of the material using a pin-on-disk machine. [Fig. 4](#) shows the pins prepared by the FDM machine.

Friction loss plays a major role in the performance and reliability of components such as plastic deformation, adhesion, wear, fracture, and fatigue, which make excessive wear a critical parameter. Testing is often used to predict friction and wear characteristics of materials that need closer investigation ([Bortoleto et al., 2013](#)). Polymers and elastomers in sliding contacts often operate in a certain set of conditions called "thermal control regime," in which the contact temperature affects the friction and wear. Adhesive wear mechanisms always occur in sliding contacts ([Lisowski and Stolarski, 1981](#)). Friction causes the asperities on one surface to become cold-welded to the other surface. The volume of material transferred for adhesive wear is proportional to the real area of contact and the sliding distance ([Archard, 1953](#)). The tribological measurement is a lengthy and expensive process ([Novak and Polcar, 2014](#)); therefore, the number of experiments should be optimum. First, the wire made of particular material from the extruder is formed, and then the wire is made to run in the FDM machine. Then, pins of a specific dimension according to ASTM standards are formed with the FDM machine. These pins are used for pin-on-disk. This machine contains a holder to hold

Fig. 4 Pin prepared by the FDM machine.

Fig. 5 Schematic of the pin-on-disk process (Kennedy *et al.*, 2015).

the pin and an E-31 disk (Ducom machine setup) on which pin is rubbed. Different sizes of holders are available. **Fig. 5** shows a schematic of the pin-on-disk process.

The disk is rotated by the motor and controlled by a manual control box provided with the machine. A weight holder is attached with a single link mechanism. As weight is put on, it exerts pressure on the holder; therefore, the pin is pressed on the disk and then the machine is set to run for a particular time (Singh, 2015). In the present study, Nylon-6 pins reinforced with different metallic fillers were used and showed much less wear compared to ABS pins. Many researchers have reported that polymers and polymer composites, when sliding against a steel counterface, have less wear due to the formation of a thin protective film (Nagaraju *et al.*, 2011). To achieve proper rubbing of the pins, the counter sliding surface for the pins was prepared by gluing emery paper (600 grit size) on a steel disk (EN-32; Hardness 65 HRC). After starting the machine, the disk starts rotating and pins start rubbing on it. Hence, the wear phenomenon begins. This machine is attached to wear and weight sensors that further send signals to the software installed on the computer system provided with the machine. Then, the software monitors the signal and graphs are formed accordingly.

The wear test was performed as per the ASTM G 99 standard under dry sliding conditions at room temperature with a sliding speed of 190 rpm, 80-mm track diameter, and 5-N load for a 10-min test run. The wear value for a standard ABS is 409 μm under the same boundary conditions used for this research work. The machine was equipped with a data acquisition system. In this study, pins were made of polymer material; therefore, the rubbing of pins on the metallic disk showed negligible wear. **Table 8** summarizes the values obtained after wear testing.

It can be clearly seen that values of Nylon-6 pins are very low compared to wear values of ABS. This may be due to the presence of metallic parts in Nylon-6, because metallic parts have high wear resistance as compared to plastic materials. After experimentation with pin-on-disk, wear track was obtained from the emery papers that were glued on the disk of the machine. **Fig. 6** illustrates the comparison of ABS wear behavior and prepared pins.

In **Fig. 6**, the wear track for ABS clearly shows the extent of wear on pins when rubbed against the disk. The amount of wear for ABS was much more than that for other prepared pins. Tracks for composite material-based pins are quite sharper than for tracks of the ABS pins. Volume loss of material generally caused by abrasion and adhesion phenomena normally starts with abrasion (Nagaraju *et al.*, 2011). To understand the wear phenomenon, SEM analysis was performed to ensure the presence of every type of particle used in the different proportions. **Fig. 7** shows SEM images of composite pins.

Table 8 Results of wear tests

Sample	Type of reinforcement	Nylon-6	Al_2O_3 150 μm	Al_2O_3 120 μm	Al_2O_3 100 μm	Wear (in μm)

10		60	13.34	13.33	13.33	118

Fig. 6 Wear track for ABS and Nylon-6 pins.

In Fig. 7, it is clearly visible that the extent of wear on developed pins is low compared to ABS pins due to the presence of abrasive particles. The presence of particles has been proven by SEM analysis (see Fig. 7).

SEM analysis of every pin was performed, which ensures the uniform presence of every type of particle used in the subsequent mixture, thereby ensuring cohesion between the printed layers. After finding the wear for the composite material, Design Expert software was used to model the wear results for the different pins. The mixture module using response surface methodology was used to model the results. This mathematical tool helps to create a mathematical model for wear results of different compositions. Tables 8 and 9 show ANOVA results for wear data.

Fig. 7 SEM results of different pin samples.

The F-value of 10.55 implies that the model is significant. There is only a 0.83% chance that an F-value this large could occur due to noise. Values of Prob>F less than 0.0500 indicate that the model terms are significant. In this case, linear mixture components AC and BC are significant model terms. Values greater than 0.1000 indicate that the model terms are not significant. If there are many insignificant model terms (not counting those required to support hierarchy), then model reduction may improve the model. The R-values along with the means and standard deviations are provided here:

SD:	9.21
Mean:	130.40
R-squared:	0.8406
Adjusted R-squared:	0.7609
Predicted R-squared:	0.4791
Adequate R-squared:	9.450

Table 9 ANOVA for mixture linear model with standard error values

<i>Source</i>	<i>Sum of squares</i>	<i>DF</i>	<i>Mean square</i>	<i>F</i>	<i>Prob>F</i>
Model	2681.78	3	893.93	10.55	0.0083
Linear mixture	2681.78	3	893.93	10.55	0.0083

Corollary total	3190.40	9			
<i>Standard error for components</i>					
<i>Component</i>	<i>Coefficient estimate</i>	<i>DF</i>	<i>Standard error</i>	<i>95% CI, low</i>	<i>95% CI, high</i>
Nylon-6	54.13	1	26.37	– 10.38	118.65
Al ₂ O ₃ 150 μm	95.33	1	11.89	66.25	124.42
Al ₂ O ₃ 120 μm	161.23	1	6.72	144.79	177.67
Al ₂ O ₃ 100 μm	143.11	1	11.95	113.87	172.35

Adequate precision measures the signal-to-noise ratio. A ratio more than 4 is desirable. The ratio of 9.450 indicates an adequate signal. This model can be used to navigate the design space.

After complete analysis by Design Expert, the following mathematical model for wear in terms of actual components was obtained (see Eq. (9)).

$$\text{Wear} = |54.13300 \times a + 136.53552 \times b + 268.33180 \times c + 232.08541 \times d| \quad (9)$$

After obtaining a mathematical model for wear, a corollary was performed in a similar way to check validity of the obtained model. Eq. (10) shows the corollary for the wear model.

$$\text{wear} = |54.13300 \times 0.6 + 136.53552 \times 0.1334 + 268.33180 \times 0.1333 + 232.08541 \times 0.1333| = 117 \text{ (predicted)} \quad (10)$$

The percentage error was below 0.8%.

Case Study 2

In the second case study, an alternative FDM filament wire was fabricated in a similar way; however, in this case study SiC and Al_2O_3 were used as reinforcements in the Nylon-6 polymer matrix. For establishing MFI, a similar number of runs were performed as shown in Table 10.

Based on Table 10, it was decided to perform the final experimentation with 125- μm SiC and Al_2O_3 because with this size of reinforcement, the MFI value is close to the MFI of commercially available ABS material (ie, 2.4 g/10 min; see S. no. 10–12, 14–18, and 20). After establishing the MFI, further experimentation was performed to observe the values for different properties. The variable input parameter in this study is only composition/proportion of reinforcement. The proportions of SiC (125 μm) and Al_2O_3 (125 μm) were varied. The spools of filament wire were prepared with a single-screw extruder, installed on an FDM machine, and checked for usability. The fixed input parameters for single-screw extruders were kept the same as shown in Table 2.

After preparation of wire, mechanical tests were performed; data obtained from those tests are shown in Table 11.

Table 11 describes the various values of MFI, peak load, yield strength, Young's modulus, and percentage elongation. Better values of different properties were obtained for some combinations. Further analysis of results is discussed in the Results section.

After inputting the data in Design Expert software (based on Table 11) and by applying Mixture Design (user-defined model with three components and four responses), the prepared model was analyzed and mathematical models were obtained and counter-verified with various derived values from actual experimentation. Table 12 shows ANOVA for the mixture quadratic model.

The F-value of 24.53 implies that the model is significant. The values of Prob>F less than 0.0500 indicate that the model terms are significant. In this case, linear mixture components ab and ac are significant model terms. Values more than 0.1000 indicate that the model terms are not significant. If there are many insignificant model terms (not counting those required to support

9	50	15	35	2.6	8.95	3.91	54.89	9.77

Note: Here a, b, and c represent Nylon-6, SiC (125 μm), and Al_2O_3 (125 μm), respectively.

hierarchy), then model reduction may improve the model. R-values along with means and standard deviations are provided in Table 13.

In Table 13, adequate precision measures the signal-to-noise ratio. A ratio greater than 4 is desirable. A ratio of 14.740 indicates an adequate signal. This model can be used to navigate the design space. After complete analysis by Design Expert, an equation for percentage elongation in terms of the actual component was obtained.

Model Validation

To validate the model, a corollary was performed with a defined set of input parameters, where total proportion weight was 1. In all the corollaries, a random set of values for a, b, and c were used. Then, the prepared models were discussed and cross-checked to verify the authenticity of empirical realtions/mathematical model.

After analyzing the results for various mechanical properties, a model was developed to predict the earliest outputs, with a, b, and c representing Nylon-6, SiC, and Al_2O_3 . To validate each mathamatical model, cross-checking was performed with a certain set of defined values given in Table 14.

After analyzing the results for various mechanical properties, a model was developed to predict the earliest outputs. Eq. (11) shows the model for the MFI percentage of the filament wire:

Eq. (11) shows the model for the MFI of filament wire

$$\text{MFI} = | -0.16157 \times a + 30.47414 \times b - 57.48014 \times c - 48.77143 \times a \times b + 123.57143 \times a \times c + 4.57143 \times b \times c | \quad (11)$$

To validate and check the adequacy of the model, a corollary was performed as shown in Table 14. Eq. (11) shows the corollary for MFI.

$$\begin{aligned} \text{MFI} = | & -0.16157 \times 0.50 + 30.47414 \times 0.1 - 57.48014 \times 0.4 - 48.77143 \times 0.50 \times 0.1 + 123.57143 \times 0.50 \times 0.4 \\ & + 4.57143 \times 0.1 \times 0.4 | = 2.43(\text{predictedvalue}) \end{aligned} \quad (12)$$

After obtaining the predicted value, the percentage error was very negligible (1.43%). Therefore, the model was found to be satisfactory.

In a similar way, the mathematical model for percentage (%) elongation has been developed and validated. Eq. (13) shows the model for percentage elongation.

$$\begin{aligned} \% \text{ Elongation} = | & + 58.23400 \times a + 849.01400 \times b - 861.86600 \times c - 1826.8000 \times a \times b \\ & + 1651.60000 \times a \times c + 56.00000 \times B \times c | \end{aligned} \quad (13)$$

The model developed in Eq. (13) was validated by performing a corollary given in Eq. (14).

$$\begin{aligned} \% \text{ Elongation} = | & + 58.23400 \times 0.50 + 849.01400 \times 0.1 - 861.86600 \times 0.4 - 1826.80000 \times 0.5 \times 0.1 \\ & + 1651.60000 \times 0.5 \times 0.4 + 56.00000 \times 0.1 \times 0.4 | = 10.4944 \text{ (predicted value)} \end{aligned} \quad (14)$$

The percentage error of the predicted value of this corollary is less than 0.09%. Therefore, the model is satisfied.

A mathematical model for Young's modulus was developed. Eq. (15) shows the model developed for Young's modulus.

$$\begin{aligned} \text{Young's modulus} = | & - 111.400 \times a - 10918.76 \times b + 13945.5 \times c + 22768.8 \times a \times b - 27158.00000 \times a \times c \\ & - 1758.00000 \times b \times c | \end{aligned} \quad (15)$$

A corollary has been performed in a similar manner to validate the model developed in Eq. (16).

$$\begin{aligned} \text{Young's modulus} = | & - 111.400 \times 0.50 - 10918.76000 \times 0.10 + 13945.50000 \times 0.40 + 22768.80000 \times 0.50 \times 0.10 \\ & - 27158.00000 \times 0.50 \times 0.40 - 1758.00000 \times 0.10 \times 0.40 | = 67.144 \end{aligned} \quad (16)$$

Table 12 ANOVA for mixture quadratic model with standard error values

<i>Source</i>	<i>Sum of squares</i>	<i>DF</i>	<i>Mean square</i>	<i>F</i>	<i>Prob>F</i>

Table 13 R-values with means and standard deviation

S. no.	SD	Mean	R-squared	Adjusted R-squared	Predicted R-squared	Adequate R-squared
1	0.70	7.26	0.9840	0.9438	N/A	14.740

Table 14 Fixed values for model validation

S. no.	a	b	c
1.	0.50	0.10	0.40

After comparison of the predicted value of Young's modulus with the actual experimental value, the percentage error was less than 1.3%; therefore, the model is adequate.

Regarding mechanical properties, a mathematical model for yield strength was finally developed and is shown in Eq. (17).

$$\text{Yield strength} = |-3.52059 \times a + 1.07217 \times b + 11.28730 \times c| \quad (17)$$

Therefore, the model was cross-checked with a corollary for validation. Eq. (18) shows the corollary for yield strength.

$$\text{Yield strength} = |-3.52059 \times 0.5 + 1.07217 \times 0.10 + 11.28730 \times 0.40| = 2.86 \quad (18)$$

These equations were solved, and it can be seen that the results of the mathematical models are quite close to the actual values. Here, the percentage error is less than 1.3%, so these results could be termed significant. Furthermore, these equations are helpful for finding compositions based on tailor-made properties just by filling the desired values.

Wear Testing

Similarly, cylindrical pins were prepared using the FDM machine and tested for wear behavior. Table 15 shows the values obtained from wear testing various pins.

After obtaining values for wear testing, the values of the wear track were obtained in a manner similar to that of a previous case study. Fig. 8 show the wear tracks for various pins.

After wear testing, SEM analysis (see Fig. 9) was performed to ensure the presence of abrasive/metallic particles in Nylon-6.

After calculating the wear for the composite material, Design Expert software was used to model the wear results for the different pins. The mixture module of the response surface methodology tool was used to model the results. This mathematical tool helps to develop a mathematical model for different results of different compositions. The values of wear, as per Table 15, were input in this tool and analyzed. Table 16 shows ANOVA for the mixture quadratic model.

The F-value of 333.22 implies that the model is significant. There is only a 0.30% chance that a model F-value this large could occur due to noise. Values of Prob>F less than 0.0500 indicate that the model terms are significant. In this case, linear mixture components AC and BC are significant model terms. Values greater than 0.1000 indicate that the model terms are not significant. If there are many insignificant model terms (not counting those required to support hierarchy), then model reduction may improve the model. The R-values along with means and standard deviations are provided in Table 17.

Adequate precision measures the signal-to-noise ratio. A ratio greater than 4 is desirable. The ratio of 47.743 indicates an adequate signal. This model can be used to navigate the design space. The values of different model components and the values of their standard errors are listed in Table 18.

After complete analysis by Design Expert software, the following equations in terms of actual components are as follows.

Wear test performance data of pins were placed into the software and the mathematical model was obtained (see Eq. (19)).

$$\text{Wear} = |-6338.60000 \times a + 653.40000 \times b - 24238.60000 \times c + 6000.00000 \times a \times b + 58960.00000 \times a \times c + 18400.00000 \times b \times c| \quad (19)$$

After development of the wear model, the feasibility of this model was counter-checked by performing a corollary. Eq. (20) shows the equation of the corollary performed.

$$\text{Wear} = |-6338.60000 \times .50 + 653.40000 \times .10 - 24238.60000 \times .40 + 6000.0000 \times .50 \times .10 + 58960.00000 \times .5 \times .40 + 18400.00000 \times .10 \times .40| = 28 \mu\text{m (predicted)} \quad (20)$$

Table 15 Results of wear tests

Mean	118.75
C.V.	4.26
PRESS	N/A
R-squared	0.9988
Adjusted R-squared	0.9958
Predicted R-squared	N/A
Adequate precision	47.743

The percentage error was less than 2.14% after comparison of the predicted and experimental values; therefore, the model was adequate.

Fig. 10 shows the comparison between the actual and predicted values of wear. An actual value is obtained from experimentation and a predicted value is suggested by the software package. Hence, it can be clearly seen that predicted values are very close to the actual values obtained from the real experimentation. Similarly, graphs were also obtained and satisfactory results were found.

**Fig. 10** Actual and predicted values of wear.

After performing both case studies, better results were obtained in terms of mechanical and wear properties. However, in the first case study, the MFI values obtained were insufficient. However, further work was performed regarding formation of filament wire by selecting appropriate values to check and analyze results for different properties.

In the second case, very good results were obtained in terms of MFI, mechanical properties, and wear properties of filament wire and pins, respectively. Wear properties obtained in both case studies were very promising.

Conclusions

The outcomes of the present work show the feasibility of developing FDM wire from alternative materials with the single-screw extrusion process. Because ABS wire has limited mechanical and wear properties, alternative materials with tailor-made properties can be used. In this case, a wire comprising alternative material has been successfully developed and pins were successfully prepared. The values for wear and MFI have been established. A Nylon-6-based feed stock filament was successfully developed with hybrid reinforcement of SiC and Al₂O₃ of different sizes. The prototype/pins comprising composite materials have been developed with high resistance to wear. The wear track obtained in this study shows that the material is highly wear-resistant. The wear model was developed and cross-checked for accuracy. The wire used as feed stock filament for FDM with tailor-made wear properties can be easily predicted by the proposed empirical model.

Introduction and Literature Review

Single and twin screw extruders (TSEs) have been used by the food industry to produce a variety of products, such as: snack foods, confectioneries, bread, pasta products, pet foods, and breakfast cereals. TSEs are more complex and costly than single screw extruders, but they possess many advantages (Akdogan, 1996). Apart from the food sector, various other industries including pharmaceutical, bioprocessing and technology, and most importantly plastic technology are incomplete when imagined without a TSE. TSEs play a major role in blending, compounding, devolatilization, reactive extrusion, and profile extrusion for various categories of materials. As a matter of fact extruders were first introduced in the plastics and food industries, in the early 20th century (Mollan, 2003), for the production of pipes and pasta products respectively. Gamlen and Eardley (1986) were one of the first to use the TSE in the pharmaceutical field. Nowadays, TSEs are applied in the pharmaceutical field for the manufacture of a variety of dosage forms and formulations such as granules, pellets, tablets, suppositories, implants, stents, transdermal systems, and ophthalmic inserts (Breitenbach, 2002). In the category of TSE, there exist two configurations of screws, corotating and counterrotating, depending upon their relative motions as shown in Fig. 1 (Martin, 2013). However, corotating TSEs were mostly used for research applications (Meijer and Elemans, 1988; Gogoi and Yam, 1994). Screw configuration is realized by a combination of screw elements; for example, feeding, conveying, mixing, or retaining functions are possible.

Due to the inherent characteristics of TSE design, variations made in barrel segments, screw elements and dosing points can be varied to adapt TSE for manufacturing of a large variety of compounds. Typical adaptations are the use of modified screw profiles tailoring the amount of mechanical mixing, residence time and pressure levels, within limits, to specific needs of the material system. Classical conveying or forwarding elements are always inserted at cylinder openings, for example, at barrel holes to convey material away from the feed opening or to discharge processed material at the end of the extruder. Kneading elements or kneading blocks, the second classical element type, are usually used when material has to be sheared and dispersively mixed. Whereas, combing mixer elements meet the challenge of conveying and mixing simultaneously. Basically they are conveying elements with longitudinal slots, without or having almost no loss in forwarding properties (Thiele, 2003). A typical sectional configuration of TSE is shown in Fig. 2.

One of the key factors to achieve desirable properties of the polymer blend is the control of morphology (Bourry and Favis, 1998). Favis and Therrien (1991) studied the morphology of polypropylene (PP) and polycarbonate modified in corotating TSE. It was found that die wall proximity, high composition, and high viscosity/elasticity ratios resulted in the preferential fiber formation in the dispersed phase. Viscosity ratio effect on phase size between TSE and an internal mixing chamber indicated a significantly coarser dispersed phase in the latter case at high viscosity ratio. However, at a lower viscosity ratio the phase size and size distribution were identical in the two processing environments. Machado *et al.* (1999) monitored the chemical conversion and morphological evolution of PA-6/EPM/EPM-g-MA blends along a TSE by quickly collecting small samples from the melt at specific barrel locations. The results show that the MA content of all blends decreases drastically in the first zone of the extruder. The extruder was found to produce insignificant changes in morphology. Sui *et al.* (2009) prepared a novel plant fiber reinforced PP composite by using a corotating TSE. It was found that there existed no filler's agglomerations, which indicated that blending by means of the TSE was an effective means for dispersing the plant fibers in the polymer matrix. In another work, Ohtsubo *et al.* (2005) developed a novel foodstuff from pregerminated brown rice through a TSE. The rice samples were subjected to extrusion cooking, immediately after the germination and adjustment of the moisture contents. Lertwimolnun and Vergnes (2006) used corotating TSE for the preparation of PP/organoclay nanocomposites with maleic-anhydride as compatibilizer. They investigated the effects of processing conditions as well as screw profile of TSE in response of forming PP nanocomposites. It has been found that the proportion of exfoliation was dependent on screw speed and feed rate. Peltola *et al.* (2006) also studied the effect of screw speed on morphology, rheological, and mechanical properties of nano-clay reinforced PP nanocomposites with aid of transmission electron microscopy, thermogravimetric analysis, rheometry, and mechanical test. The results of the study highlighted that nanocomposites showed both intercalated and exfoliated structures depending on the screw speeds of the extruder. Hsieh *et al.* (1989) also considered screw speed as one of the input parameters for processing of corn meal. Jesus *et al.* (2016) blended poly (L-lactic acid) (PLA) and silver (Ag) particles through melt processing by using a TSE. The concentration of silver particles in nanocomposites were kept at 0.1, 0.2, and 0.3 wt%, which resulted in enhancement of thermal and mechanical properties of poly (L-lactic acid). Fig. 3 shows the results of thermal and mechanical properties of the TSE processed nanocomposites.

It has been found that with an increase in the wt% of Ag nanoparticles in PLA the resulting heat capacity of the nanocomposite wires was increased, while on the other side their tensile strength was decreased. Further, it is highlighted here that the TSE processed PLA attained more heat capacity compared to unprocessed PLA while maintaining its tensile strength. Lee and Han (2000) conducted

a “screw pullout” experiment and investigated the evolution of blend morphology, determined by scanning electron microscopy, along the TSE axis by putting emphasis on the effects of viscosity ratio, blend composition, and processing variables (barrel temperature profile and screw speed). Four blend systems based on the difference in the melting temperature, namely, polystyrene (PS)/poly(methyl-methacrylate), PS/polycarbonate, PS/high-density polyethylene, and PS/PP, were selected. The results of their study outlined the capability of TSE for uniform blending. Biobased polyamide was reinforced with 20 and 30% chopped cellulosic fiber (by wt%), with corotating TSE, for addressing important applications of material science and meeting the rising demand for

Fig. 4 Fiber distribution and fiber pullout in compounds with 20 wt% fiber content processed using different screw configurations. Twin screw extruder (TSE) configuration C1 (a), configuration C2 (b), single-screw extruder at T1 temperature profile (c), and configuration C2 at T2 temperature profile (d) (Reproduced from Feldmann, M., Heim, H.P., Zarges, J.C., 2016. Influence of the process parameters on the mechanical properties of engineering biocomposites using a twin-screw extruder. Composites: Part A 83, 113–119.) (Note: T1 and T2 are the temperature profiles of screw as given in Feldmann *et al.* (2016)).

sustainable materials (Feldmann *et al.*, 2016). The micrographical analysis shows the effect of screw configuration on the distribution of the cellulose fibers in the matrix material. Compounds prepared with TSE (refer to Fig. 4(a), (b), and (d)) and single screw extruder (refer to Fig. 4(c)) were compared.

It has been found that there was no significant difference in the fiber distribution, which indicated some agglomerates due to the lack of mixing elements and kneading disks in screw configurations C1 and C2 as shown in Fig. 2. Villmow *et al.* (2008) used corotating TSE for dispersion of multiwalled carbon nanotubes in PLA. The composites were prepared with four different proportions of carbon nanotubes, screw profile, temperature profile, and rotation speed under different processing conditions. Transmission electron microscopy was performed to observe the dispersion and network formation in the submicron scale. High rotation speed that ensured a certain residence time of the melt combined with a screw profile containing mainly mixing elements were found to be highly convenient to disperse and distribute the nanotubes in PLA. Similarly Jonooobi *et al.* (2010) developed cellulose nanofiber (1, 3, and 5% by wt.%) reinforced PLA by TSE. Morphology, mechanical, and dynamic mechanical properties were studied theoretically and experimentally to see how different cellulose nanofiber concentrations affected the properties. It has been found that the tensile modulus and strength increased from 2.9 to 3.6 GPa and from 58 to 71 MPa, respectively (for 5 wt%). Further dynamic mechanical test showed that the storage modulus increased for all nanocomposites as compared to PLA. Verma (2016) discussed about the nanoclay reinforcement in a polymer matrix and its effect on various mechanical properties such as tensile strength, tensile modulus, flexural strength, flexural modulus, impact strength, etc. Recently, Upasani *et al.* (2016) used TSE for the preparation of ZnO/MWCNT/PP composite films, which were characterized by differential scanning calorimetry (DSC), thermal gravimeter, reflectance, X-ray diffraction analysis, and scanning electron microscopy. The composite films showed antibacterial and antifungal properties, improved fire resistance, and lower combustion toxicity compared to neat PP film. Along with this, camouflage applications and very good antistatic properties made these films suitable for multiple hazard protections. From the literature review, it has been found that there exist many processing variables on which the quality characteristics of the

Fig. 5 Fish bone diagram relation between twin screw extruder (TSE) parameters and product's quality characteristics.

resulting blend/composite/film depend. **Fig. 5** shows the fishbone diagram highlighting the important input variables for product quality.

Extrusion of Polymeric Composite Feedstock

Polymer nanocomposites are an emerging class of materials that have properties that are often superior to conventional composites and may be synthesized using surprisingly simple and inexpensive techniques. For about a half century, an extensive research effort has been witnessed in the incorporation of metal nanoparticles into a polymer matrix. This interest arises in polymer composites since they can preserve the mechanical properties of the polymer matrix but can benefit in heat conduction properties due to the inclusion of metal fillers (Gul and Shenfill, 1984). Among the various nanosized metal particles, gold and silver were frequently used as nanofillers for polymer matrices due to their good conductivity and chemical stability (Zhu *et al.*, 2016). Nanoparticle composites contributed to the development of future data storage, optical and electrorheological materials or display devices (Schmidt and Malwitz, 2003). Since the documented discovery of carbon nanotubes (CNTs) in 1991 by Iijima (1999) and the realization of their unique physical properties, including mechanical, thermal, and electrical, many investigators have endeavored to fabricate advanced CNT composite materials that exhibit one or more of these properties (Biercuk *et al.*, 2002; Ounaies *et al.*, 2003; Weisenberger *et al.*, 2003). CNTs are quite effective compared to traditional carbon black microparticles, primarily due to their large aspect ratios (Colbert, 2003). The properties and applications of CNTs and related materials have been very active research fields over the last decade (Guldi *et al.*, 2005). CNTs possess high flexibility, low mass density, and large aspect ratio (typically >1000), whereas predicted and some experimental data indicate extremely high tensile moduli and strengths for these materials. Individual single-walled carbon nanotubes (SWCNTs) can be metallic or semiconducting. The latter can transport electrons over long lengths without significant interruption, which makes them more conductive than copper (Durkop *et al.*, 2004). The effect of CNT alignment on percolation conductivity in SWCNT/PMMA composites has been investigated by Du *et al.* (2003). The SWCNTs were aligned by melt fiber spinning, and various levels of alignment could be obtained by controlling the extensional flow in the spinning process. SWCNTs consisted of a single graphite sheet seamlessly wrapped into a cylindrical tube whereas multiwalled carbon nanotubes (MWCNTs) comprise an array of such nanotubes that are concentrically nested like rings of a tree trunk (Baughman *et al.*, 2002). Similarly, copper (Cu) nanopowder (CNP) also has a very rich contribution to the development of conductive polymeric composites. Conductive polymer composites have been intensively studied due to their many advantages, including good processability, corrosion resistance, comparatively low weight, and low cost (Li and Sundararaj, 2015). Compared with nanoparticles, nanowires (NWs) have smaller dimension structure and high aspect ratio, which could efficiently transport electrical and thermal carriers along one controllable direction (Hu *et al.*, 1999). Cu in nanorange has recently garnered increasing attention as an excellent candidate for transparent conducting films (Nam and Lee, 2016). Cu has high intrinsic conductivity, and is a potential alternative to indium tin oxide and silver NWs. Cu is only 6% less conductive than silver, and is very abundant and 100 times less expensive than indium tin oxide and silver (Jewell and Kimball, 2014).

The feed stock filament can be produced with two techniques: capillary or piston extrusion and screw extrusion (Seyi *et al.*, 2001). Piston extrusion is used for fabricating filaments in small quantities that are used for trial runs only. Screw extrusion is used for continuous production of filaments. Size of a single screw extruder is specified with screw diameter and L/D ratio. Single screw extrusion is the most cost-effective and effective way to melt and pump a polymer (Pan *et al.*, 2012). The various process variables of the screw extrusion process are screw speed, barrel temperature, die temperature, water tank temperature, and take-up unit speed. The optimum value of all these parameters should be required for the fabrication of a continuous, homogenous, flexible filament with consistent diameter or varying within the limits. Thermocouples are attached at various sections of the screw extruder, to monitor temperature changes during the processing of material. Chamil *et al.* (2011) generated a nonlinear model of die melt temperature profile in order to predict the die temperature with the help of thermocouple mesh and used it for selecting the optimum process setting for improving process homogeneity. For fused deposition modeling (FDM) feedstock filament the

desired value of diameter is 1.75 mm. The feedstock filament generally accomplishes two functions: one is to feed material and second is to act as a piston to force material through a capillary tube. If the filament diameter is less than the desired value, the flow rate of material through the liquefier head becomes low and creates roads with smaller width and thickness. This results in poor bonding between adjacent roads and layers and creates voids and air gaps, which decreases mechanical strength and surface finish of parts. If the diameter is more than the desired value, then either the filament is not fed properly into the liquefier head through the capillary tube or it increases the flow rate of material and decreases dimensional accuracy and surface finish. The overflow of material from the capillary tube may damage the internal circuits of the liquefier head. The circularity or ovality of the diameter should be within limits for continuous feeding and proper gripping of filaments between the rollers. The single screw extrusion process consists of four units: PLC unit, screw extruder, water tank, and take-up unit. The PLC unit contains various electrical circuits and servo drives for the proper coordination and smooth functioning of the extruder. The most important part of the screw extruder is the screw. The conventional single screw extruder, also called a plasticating extruder, is composed of three sections: the feeding section, compression section, and metering section. The material enters inside the barrel through a hopper. The feeding is either by gravity or by screw. In the feed section the material is moved from the hopper and preheated. The heated material is compressed in the compression section and pressure starts building inside the screw barrel. The material is transformed into fluid; air mixed with pellets is extracted from the melt. In all screws at least the first 70% or so of melting is due to the shear stress in the melt film between the barrel and the solid bed surface. In the metering section, the various ingredients of melt are homogeneously mixed and sufficient pressure is developed to pump it through the die opening. Due to high pressure developed inside the barrel, the melt is forced to the die zone. Before reaching the die, the melt passes through a screen pack, a series of wire meshes supported by a stiff plate containing small axial holes. The screen pack performs two functions. The first is to filter out contaminants and hard lumps and the second is to build sufficient pressure in the metering section required for the extrusion process. The pressure is developed during the extrusion process in various sections. Screw design is selected according to the type of material to be processed. The melt pressure developed inside the screw not only depends upon optimum parameters but also on material properties and machine geometry (screw channel depth, barrel diameter, surface conditions of the barrel and screw, barrel thickness). Singh and Singh (2014) developed a cost-effective nylon-based feedstock wire FDM machine. They have intended to replace commercially available ABS with Al_2O_3 reinforced nylon wire without changing any hardware or software in the machine. A single screw extruder was used for wire preparation and wire thus produced was tested on FDM for its mechanical properties, such as tensile strength and percentage elongation. Šafka *et al.* (2016) dealt with specific polymer composites that were modified for FDM. These two phase systems involved thermoplastic matrix filled with natural fibers to put FDM technology on the accuracy of the semiproduct formed into the filament shape. Individual steps of the polymer composite palletization and the following preprocessing and processing activities were described in their work. Sa'ude *et al.* (2016) developed Cu powder filled polymeric composite filament for FDM applications. The dynamic mechanical testing highlighted that the addition of Cu powder resulted in an increase in the storage modulus, loss modulus (E''), and tan delta of the resulting parts. Recently, the company Graphene 3D Lab has proposed a commercial plastic/graphene composite filament for printing of graphene-enhanced plastic structures using a conventional FDM printer (Kim *et al.*, 2015). Recently, it has been reported that the addition of nanomaterials such as carbon nanotubes, NWs and quantum dots to host matrices like polymers, metals, and ceramics via additive manufacturing/3D printing has the potential to enable greater capabilities in nanocomposite production (Campbell and Ivanova, 2013). This could be achieved by either printing the two ingredients side-by-side (i.e., on the previously described geometrical areas) or by premixing of the nanomaterials into the host matrix and followed by 3D printing of the nanocomposite mixture as a complete part. For the first, one needs to modify the hardware or even redesign the deposition strategy along with adjusting computer insight. However, both of the two are not required for the second option but synthesis of the composite filament, having controlled dimensions, could be tedious. This is for sure that the parts produced via second way will possess better mechanical/electrical/thermal properties as compared to the first one since the geometrical features are easily controllable through computer insights.

In this we have developed a composite feedstock filament consisting of biocompatible poly-vinyl-chloride/polypropylene (PVC/PP) blend in 70/30 wt% ratio. This blend was reinforced with 4 wt% of nano hydroxyapatite (n-HAP) filler and mixed in the form of FDM filament with the help of corotating TSE; HaaKE miniCTW (make: Thermo Fishers) as shown in Fig. 6. The high grade PVC and PP were purchased from (Batra polymers, Ludhiana (India)), having melt flow index (MFI) 35–38 g/10 min and 13–17 g/10 min, respectively, were used to prepare a polymer blend that was further reinforced with n-HAP powder (ranges from 53 to 150 nm) as shown in Fig. 7. The n-HAP powder was supplied by Nanoshel, India.

Composite Filament Extrusion

Several methods can be used to produce a uniform filament; one is continuous extrusion to the filament winder, but the filament stuck together and became very thin. Another is a water-bath to quench the filament and maintain the diameter, but the water-bath did not fit directly next to the extruder and the filament still stretched. In this study, we have selected prepared hybrid feedstock composite filaments with different proportions of filler as shown in Table 1. The extrusion parameters were selected on the basis of thermograph of virgin PVC and PP as shown in Fig. 8(a) and (b), respectively. From this graph it has been found that the glass transition and thermal melting of PVC and PP took place between 159 and 163°C, respectively, hence the extrusion temperature for composite feedstock filaments was selected slightly on the higher side, i.e., 180–200°C, due to presence of fillers. Different levels of extrusion speed were also selected and diameter of the feedstock filament was maintained at 1.75 mm.

Fig. 7 Micrograph of nano hydroxyapatite (n-HAP).

In the present case, a forced convection method was used wherein a fan was cooling the extrudate to fix its dimensions and the windup was carried out manually. Since the mass intake of TSE used in the present study is much less, limited to few grams only, it was not possible to produce a long length of the feedstock filament. However, we were able to develop sufficient lengths of feedstock to fulfill the material consumption by the FDM printer. [Table 1](#) shows the control log of experimentation and [Fig. 9](#) shows the few samples of in-house developed feedstock filament samples.

Rheological Properties of Filament

Rheological properties of the polymeric composites play an important role before allotment of specific application. Oscillatory melt rheology is known to be a very sensitive method to characterize the structure of polymer melts as in literature it described the interconnected structures of anisometric fillers, which led to qualitative changes in the spectra of dynamic moduli and viscosity ([Pötschke et al., 2004](#)). In case of composites with conductive fillers, it has been earlier reported that melt viscosity of the composites was increased whereas variation of processing viscosity was reduced ([Kuan et al., 2005](#)). Recently, the rheological properties of extruded composite filaments were extensively studied with the help of melt flow indexer as per ASTM-D-1238(10)

standard (Garg and Singh, 2016; Boparai *et al.*, 2016). In the present work, the extruded composite filaments were palletized, manually, and thus used for melt flow analysis. The extrusion weight and temperature were kept constant at 3.8 kg and 220°C respectively. Table 2 shows the output in terms of melt weighed in a 10-min time duration. Fig. 10 shows the S/N response of input process variables on MFI of composite feedstock filament materials.

Fig. 10 outlined that in case of screw speed, with an increase in the speed revolutions the resulting MFI values were increased. This might be due to the fact that during filament preparation with TSE, screw speed enhanced the molecular bonding due to which melting of composite materials in the melt flow indexer took place uniformly. The same trend has been also observed in case of extrusion temperature wherein increase in temperature increased the MFI due to the obvious reasons discussed above. However, extrusion load is found to be unaffected in terms of MFI of the feedstock filaments prepared with TSE. Table 3 shows the

Table 2 Results of melt flow index (MFI)

S. No.	Average MFI (gm/10 min)	S/N ratio (dB)
1	14.35	23.1370
2	13.55	22.6388
3	19.60	24.4022
4	16.34	23.7165
5	15.61	23.8681
6	21.45	24.8905

**Fig. 10** S/N response of input variables to melt flow index (MFI).

analysis of variance of S/N ratio of input parameters for MFI. From this analysis it has been found that no input parameter has statistical significance for the recorded MFI values at 95% confidence level.

Whereas the percentage contribution of sources; screw speed, extrusion temperature, extrusion load and error is recorded as 45.43, 50.55, 0.26, and 3.75%, respectively. Since the error is less than 5%, it can be outlined that the experimental and measurement errors are within the acceptable range. Further, we have predicted the optimized value of MFI by using the values given in Table 4.

Eq. (1) was used for the prediction of optimized MFI value:

$$\eta_{\text{opt}} = m + (m_{\text{Amax}} - m) + (m_{\text{Bmax}} - m) + (m_{\text{Cmax}} - m) \quad (1)$$

In Eq. (1), “ m ” is overall mean of S/N data (calculated in Table 4); “ m_{Amax} ” is the maximum mean of S/N data for parameter A, i.e., at level 3; “ m_{Bmax} ” is the maximum mean of S/N data for parameter B, i.e., at level 3; and similarly “ m_{Cmax} ” is the maximum mean of S/N data for parameter C, i.e., at level 1. The corresponding optimum MFI value is calculated using Eq. (2):

$$\gamma_{\text{opt}}^2 = 1/10^{-\eta_{\text{opt}}/10} \quad (2)$$

and,

$$\gamma_{\text{opt}} = 19.71 \text{ gm/10 min (predicted value)}$$

For the verification of the calculated value, a confirmatory experiment was performed at the best setting (i.e., A₃B₃C₁) for hardness, which shows 19.79 g/10 min, which is very close to the predicted value.

Table 3 Analysis of variance of S/N ratio for melt flow index (MFI)

Source	Degree of freedom	Sum of square	Variance	Fisher's value	P-value	Contribution (%)

Thermal Analysis of Filament

Mechanical and electrical properties have been extensively studied whereas thermal properties like glass transition temperature, melt enthalpy, degradation at higher temperature, etc., are less investigated. Thermal energy storage in the form of latent heat is one of the most efficient methods for thermal energy storage. Due to high storage density and almost constant temperature during phase transition phase change materials are widely used for storing thermal energy (Dincer and Rosen, 2002; Pielichowska and Pielichowski, 2014). DSC was introduced in the form of commercial instruments during the early 1960s and it has been found to provide a convenient and useful method to measure the glass transition (T_g), enthalpy in melting (ΔH_m) and crystallization temperatures (C_T) of uncured and cured laminates and also the degree of cure of the final product, the heat of reaction during processing. Its main advantages are the modest requirements in terms of sample size (~ 20 mg) and its ability to provide quantitative data on overall reaction kinetics, with relative speed and ease (Barton, 2004). Presently, DSC (make: Mettler Torledo, Switzerland) was used to study the thermal characteristics of resulting composites. Initially thermal test was carried out under dynamic heating as follows: (1) first heating from 30 to 300°C @ 10K/min incremental rate under dry N₂ atmosphere (50 mL/min); (2) first uncontrolled cooling from 300 to 30°C under dry N₂ atmosphere; (3) second heating same as (1); and (4) second cooling same as (2). From Fig. 11, it has been found that the decomposition of the composite mixture took place after 220°C thereby further thermal treatment of steps (2), (3), and (4) did not given any valuable information. In the next iteration, we have modified the thermal treatment of dynamic heating accordingly. So, the rest of the tests were performed as follows: (1) first heating from 30 to 220°C @ 10K/min incremental rate under dry N₂ atmosphere (50 mL/min); (2) first uncontrolled cooling from 220 to 30°C under dry N₂ atmosphere; (3) second heating same as (1); and (4) second cooling same as (2). The respective thermographs are given in appendix A. Here, we have considered the difference of enthalpies of melting during first and second heating as output response. Since it is general fact that some of the polymeric materials started to lose their thermal properties after periodic thermal treatments, in the present case it will be very interesting to understand the effect of TSE parameters on succeeding thermal characteristics of the resulting filament materials. Each time we have recorded some degradation of the polymer composites due to which these materials have taken lesser enthalpy during second heating. Along with this we have also calculated the glass transition temperatures and enthalpy of condensation as given in appendix A. However, melting enthalpy has been only taken into consideration and is studied with response of TSE parameters. The resulting numerical values of ΔH_m ($\Delta H_1 - \Delta H_2$) as given in Table 5 were optimized. From Fig. 12, it has been found that with an increase in the screw speed the ΔH_m value was reduced, which means the resulting composite filament possessed better thermal properties in succeeding heat treatment cycles. This is mainly due to the fact at higher speed the molecular bonding was stronger as compared to lower speed. In this case, extrusion temperature did not play an important role since the slope for this parameter is lying along the mean line. However, in case of extrusion load, it has been found that the ΔH_m values were increased with an increase in the extrusion load. It is difficult to explain the reason behind this trend without performing spectroanalysis, which is part of our upcoming research. From analysis of variance, given in Table 6, it has been found that no input parameter has statistical significance for the recorded ΔH_m values at 95% confidence level.

For this response parameter, optimized value was also calculated by using the values of Table 7.

Eq. (1) was used for predicting optimized S/N ration of ΔH_m . The corresponding optimum hardness value is calculated using Eq. (3):

$$\gamma_{\text{opt}}^2 = 1/10^{\eta_{\text{opt}}/10} \quad (3)$$

$$\gamma_{\text{opt}} = 0.46 \text{ J/gm (predicted value)}$$

Fig. 11 Thermograph for sample 1 of Table 1. DSC, Differential scanning calorimetry.

Table 5 Results of ΔH_m

S. No.	ΔH_m (J/gm)	S/N ratio (dB)
1	1.43	-3.1067
2	1.81	-5.1536
3	3.23	-10.1841
4	1.8	-5.1055
5	3.39	-10.6040
6	0.7	-3.0980
7	1.05	-0.4238
8	0.55	-5.1927
9	0.98	-0.1755
Overall mean S/N ratio, m		-4.78266

For the verification of the calculated value, a confirmatory experiment was performed at the best setting (i.e., $A_3B_3C_1$) for ΔH_m , which shows 044 J/gm, which is very close to the predicted value.

Peak Strength

The peak strength of the in-house extruded feedstock filaments was tested according to ASTM-D412 standard. Specimen sample for tensile testing is shown in Fig. 13, and was tested on a universal testing machine (make: Shanta Engineering, Pune). The results of the tensile test are summarized in Table 8. Fig. 14 shows the S/N response of input process variables on peak strength of the resulting composite filaments. From Fig. 14, it has been found that variation in parametric levels of screw speed did not have any effect on the output response. However, in case of extrusion temperature it has been found that with an increase in the temperature the peak strength of the extruded filaments was also increased. This can be explained by the fact that at higher temperature the mixing of the n-HAP powder particles in polymeric blend is more uniform as compared to the lower levels of the temperatures. The better mixing or uniform distribution of n-HAP particles resulted in improved mechanical properties under tensile load. Further, in case of extrusion load a minor dip has been observed while increasing the extrusion load from 10 to 15 kg. However, further increase in extrusion load resulted in an increase in the peak strength. Table 7 shows the analysis of variance of S/N ratio for

Fig. 12 S/N response of input variables to ΔH_m .

Table 6 Analysis of variance of S/N ratio for ΔH_m

Source	Degree of freedom	Sum of square	Variance	Fisher's value	P-value	Contribution (%)
Screw speed (rpm)	2	98.807	49.404	4.63	0.178	41.23
Extrusion temperature (°C)	2	2.228	1.114	0.10	0.905	0.93
Extrusion load (kg)	2	117.076	58.538	5.49	0.154	48.89
Error	2	21.342	10.671			8.9
Total	8	239.453				

Table 7 Response of S/N ratio for ΔH_m

Level	A (rpm)	B (°C)	C (kg)
1	-6.148	-2.879	-1.728
2	-4.204	-3.522	-3.361
3	-1.648	-2.304	-7.071
Delta	7.796	1.218	8.799

input variables. From this table, we have found that only extrusion temperature is significantly affecting the peak strength as its p -value is less than 0.05, highlighting its significance at 95% confidence level. Overall from these results, we have come to understand that extrusion speed and extrusion load are not relevant parameters as far as the peak strength of the composite polymer feedstock is concerned.

From Table 9, it has been found that the percentage contribution of screw speed, extrusion temperature, extrusion load and error is 0.09, 77.92, 18.92, and 3.01%, respectively. The contribution of error (less than 5%) here signifies that the experimental errors incurred during part preparation and testing are under control.

Similarly, we have predicted the optimized value of peak strength of composite feedstock filament by using the values given in Table 10, as per Eq. (1).

Fig. 13 Universal testing setup; (a) specimen dimension and (b) testing of sample.

Table 8 Results of peak strength

S. No.	Peak strength (MPa)	S/N ratio (dB)
1	16.6	24.4022

Table 10 Response table of S/N ratio for peak strength

Level	A (rpm)	B (°C)	C (kg)
1	25.75	24.78	25.50
2	25.70	25.77	25.40
3	25.69	26.59	26.23
Delta	0.06	1.81	0.82
Rank	3	1	2

We got the optimized value of peak strength from Eq. (2):

$$\gamma_{\text{opt}} = 22.73 \text{ MPa (predicted value)}$$

Similarly, the predicted value was verified by performing a confirmatory experiment at optimized settings of input variables, i.e., A₁B₃C₃, which resulted in peak strength of 22.62 MPa, very close to the predicted value.

End Note

TSE has brought a revolution in material extrusion in tasks like compounding/blending of suitable proportions of different ingredients as practiced in the area of pharmaceuticals, polymer technology, food processing, bioprocessing and technology, etc. It has been found that TSE process parameters have a valuable effect on the various mechanical properties (such as tensile strength, tensile modulus, flexural strength, flexural modulus, impact strength, etc.) of reinforced polymer extrudate. In the present article we have developed n-HAP reinforced PVC/PP blended feedstock filaments for FDM applications. A design of experiment was employed to find out the effect of TSE parameters on rheological, mechanical, and thermal properties of extruded filaments. From this article, we have come to know that only extrusion temperature has significantly affected the peak strength of the filament whereas all other output responses were unaffected by input variables of the TSE. The mathematical model developed to predict the optimized values of output responses was thoroughly verified through performing confirmation experiments. Future research efforts are focused on in-depth investigation of the morphology of the produced feedstock filaments.

Acknowledgment

For the present article, the authors are highly grateful to the Science and Engineering Research Board (DST, GoI) for providing us financial support and to our postgraduate students Nishant Ranjan and Ravinder Sharma for their help while doing experimental work.

Saad, The Effect of In-Situ-Formed Silver Nanoparticles on the Morphological Properties of Epoxy Resin Filled Composites, In Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2019, doi:10.1016/B978-0-12-803581-8.11359-1.

Introduction

Conductive ink is a special type of ink, which allows electric current to flow through it. The ink can be printed directly on a substrate or any flexible surface through a regular printing process. There are several varieties of conductive ink in the market and it is crucial to choose the suitable ink for any electronic application. The ink is usually applied to the substrate and slightly heated to evaporate the solvent and heat up the conductive particles together. Conductive ink is a significant component of any application, with extensively uses in photovoltaic cells, medical devices, membrane switches, as well as RFID chips. It is regarded as the next generation of an electronic device (Mohklis *et al.*, 2018).

Besides that, conductive ink, which is an ink printed to conduct electricity have been in some talk for a few years for their applications in printed electronics (PE) and flexible electronics (FE), respectively. It has the ability to print circuits on paper or some form of flexible surface through the inkjet printing technology. Although the early growth of the printed electronics industry is not as drastic as expected, there are some great demands to use these products (conductive inks) in daily activities such as cell phones, displays, smart wearable, lighting, small packaging, labels, shipping, storage and many more (Hamidi *et al.*, 2018). Conductive ink has been widely studied due to its popularity in printed electronic and demand from the market.

The process of choosing the right ink loading is a crucial successful factor for quick, simple and affordable production of PE prototypes and electronically functional prints. It is mainly based on the electrical properties of the conductive ink itself. In this experiment, the investigation in the characterization of conductive ink is related to the formulation of ink loading and preparation method of the ink samples (Lee and Oh, 2010).

Conductive ink is an innovation through research that had been conducted, which able to reduce cost and accelerate the fabrication of electronic components (Zheng *et al.*, 2013). There are many advantage of this technology such as its capability to print a controlled amount of ink at high frequency and on almost any type of substrate, low cost, additive and efficient handling of expensive materials. The materials of conductive filler vary in shapes and sizes, which consist of metal properties such as carbon (C), copper (C), gold (Au), and silver (Ag) particles (Mohklis *et al.*, 2018; Kamel *et al.*, 2018). There are many types of stretchable substrate that can be used in conductive ink like glass slide substrate, polyethylene terephthalate (PET), thermoplastic poly urethanes (TPU), polyurethane (PUT), and poly dimethyl siloxane (PDMS). Basically, these substrates do not tend to be very smooth and have a very low glass transitions temperature (T_g). Therefore, the temperature during curing process is generally under 150°. Another challenge regarding the ink substrate is the compatibility issue, which can cause metal delamination under mechanical and thermal stresses. These stretchable substrate tends to be quite thin (1–5 mils thick), hence they are easily stretched. Therefore, it can easily deform when the printing process takes place and leads to distortion in the printed image (Mohklis *et al.*, 2018).

In this article, it elaborates the effect of in-situ formed silver nanoparticles on the morphological properties of epoxy resin filled composites, which may become a future reference on macrostructure technology development.

Results and Discussion on Morphological Analysis

Ink Formulation

For the formulation of conductive ink in this experiment, the materials used are shown in Table 1. The material composition with various percentages is tabulated in Table 2.

The material composition starts from the least percentage of filler until the highest percentage of filler. The loading of hardener is 30% of the amount of binder loading. Total value from the table is the sum of filler loading and binder loading amount and it was set before the formulation process started, which is 2 g.

In-Situ Experimental Setup

In Lu (2013) defined the microscopy as a method that provides the measurements of particle shape and size, morphology and the dispositions of nanoparticles by producing two-dimensional pictures of three-dimensional items. Fig. 1 shows the setup for in-situ morphological analysis.

Table 1 Materials used in ink formulation

Materials		
Silver nanoparticles (AgNPs)	Epoxy	Hardener
		
Used as the filler element	Used as the binder element, to bind the particles together	Used to harden or dry the mixture

Table 2 Composition of ink loading

Sample	Filler		Binder		Hardener (g)	Total (g)
	(%)	(g)	(%)	(g)		
1	10	0.2	90	1.8	0.54	2

9	90	1.8	10	0.2	0.60	2

Fig. 1 Setup for in-situ morphological analysis.

The microscope used in this experiment was connected to the computer so that the images from the microscope could be directly displayed on the screen. The sample was placed on the stage and it was held by the stage clips as can be seen in [Fig. 2\(a\)](#). The revolving turret was turned in order to secure the position of the required power objective lens. In this experiment, three power objective lens were used, which were 5x, 10x and 20x. Next, the focus knob was turned to move the stage upward or downward

Fig. 2 (a) Sample was held by stage clips and (b) Light was directed to the position.

Fig. 3 Sample of morphological analysis for silver nanoparticles conductive ink.

without having the objective lens in contact with the sample until the light was directed to the desired position as shown in **Fig. 2 (b)**. The focus knob was turned until the image had been into focus mode.

After a clear image of the sample was obtained, the image was recorded in the computer and the scale of the image was set up at 100 μm . Those described steps were repeated for another power objective lens as at each point; three images with different resolutions (5x, 10x and 20x) were required in this experiment. **Fig. 3** shows the sample of morphological analysis for silver nanoparticles conductive ink.

Morphological Setup

Light microscopy was conducted on the sample ink tracks to investigate the ink track in a microscopic condition. In this section, all of the microstructure images were divided into three categories, which were microstructure with no conductivity, microstructure that should have conductivity and microstructure with conductivity. The microstructure images were organized in accordance to their filler loading with three scales of magnification; 5x, 10x and 20x.

Table 3 discusses about the microstructural transformation of silver nanoparticles ink based on the filler loading in the range of 10% until 50%. For 10% of filler loading, the microstructure shows no appearance of silver nanoparticles element due to lack of filler loading as compared to the amount of binder and hardener. The binder and hardener conquer all over the ink track and if the conductor materials are low in quantity (Nash *et al.*, 2015), there is no conductivity at all. In overall, the 10% of filler loading only creates the formation of voids. While at 20%, 30% and 40% show the existence of gaps between silver nanoparticles. The frequency of gaps between silver nanoparticles can affect the electrical properties of the conductive ink layer as the increasing number of gap causes the resistance to increase. High voltage is required to ensure there is flow of current among the silver nanoparticles (Kazani *et al.*, 2012). Next, percentage of filler loading of 50% shows the presence of silver nanoparticles but in a very small quantity, which may be due to the same ratio of filler to binder.

Table 3 Microstructure with no conductivity at filler loading of 10%–50%

Filler (%)	Magnifications		
	5 ×	10 ×	20 ×
10			
20			
30			
40			
50			

Then, **Table 4** shows the filler loading that has contributed to the conductivity of the ink. The percentage of filler loading are from 60% to 80%. They display no outstanding difference between each other either in the shape of particle or size as compared to the filler loading at 90%. At 60% and 80%, the ink layer has the presence of granular-like particle. In order to be a conductive ink, the granular particle must contain a 3D connection of conduction, which leads to the existence of particle necking as discovered by researchers in 2005 (Kim and Moon, 2005).

Kim and Moon also believed that the necking growth provides a continuous connection and once the interparticle neck has been produced, the granular-like particle will be conductive although it is still porous. However, at first the 70% of filler loading does not show any traces of conductivity although it is expected to have the existence of conductivity in the ink layer. Based on the microstructure images, there have been some traces of scratch developed in the ink layer, which may be due to some mistakes happened during the printing process as it was manually deposited onto the substrate. After multiple times of fabricating the ink with 70% filler loading, finally the trace of resistivity within the ink can be identified with try and error process.

At 90% of filler loading, the dark color in the microstructure represents the presence of silver while the brighter region is the binder. Once it has already been melted, major changes can be noticed as most barriers between particles are vanished as discovered by researchers in 2011 (Kamyshny *et al.*, 2011). This indicates that the ink layers have a close-packed structure where

Table 4 Microstructure with conductivity of filler loading from 60% to 80%

Filler (%)	Magnifications		
	5 ×	10 ×	20 ×
60			 Granular particles
70	 Scratch lines		
80			
90			 Continuous particles

the particles create a strong bond between each other. Once the silver nanoparticles are in contact with each other, the particles become more continuous rather than being in the shape of discrete and spherical, thus the contact area between particles becomes bigger. Roberson explained that the increase of conductivity can be discussed only by the size of contact area through the percolation theory (Roberson *et al.*, 2011). In 2017, Jiang believed that the percolation theory can explain the situation of potentially the percolation can happen between each other when electricity flows through the structure of silver nanoparticles. The probability is based on the sintering process, where the probability is very low. The best percentage can also be achieved and this percentage is known as the percolation threshold (Jiang, 2017).

Relationship Between Rate of Resistivity, Surface Roughness and Morphological Analysis

Table 5 exhibits three parameters of each composition of sample, which are total average values of resistivity, total average values of resistivity and microstructure in order to construct a study of the relationship between sample composition and those three parameters.

For 10% until 50% of filler loading, there is no resistivity value that can be detected by four-point probe because the filler composition is low. Material of the filler is silver nanoparticles, which is widely known as conductor. So if the amount is low, it is possible that there is no resistivity that can be traced. Furthermore, the total average values of surface roughness are in the range of 0.1–1.2 μm and the total average values of surface roughness between horizontal and vertical direction show small difference. The difference indicates that the spreading of ink makes the surface to have stable consistency of irregularities. On top of that, the ink

Table 5 Comparison between rate of resistivity, surface roughness and morphological analysis

Filler (%)	Binder (%)	Point	Resistivity (Ω/sq)	Surface roughness (μm)		Microstructure (Magnification of $20\times$)	
			Total Average at Positions A & B	Total average at positions A & B			
				Horizontal direction	Vertical direction

		2	0.228	0.276			
		3	0.121	0.114			
20	80	1	–	0.943	0.689	Dark spot is presumed as AgNPs	
		2	1.507	0.229			
		3	1.135	0.111			
30	70	1	–	0.952	0.686	Dark spot is presumed as AgNPs	
		2	1.506	1.033			
		3	1.116	1.097			
40	60	1	–	0.469	0.561	Dark spot is presumed as AgNPs	
		2	0.228	0.364			
		3	0.340	0.300			
50	50	1	–	0.502	0.245	No obvious color difference due to the same amount between filler and binder	
		2	0.439	0.240			
		3	1.071	0.383			
60	40	1	136.148	4.238	4.264	Darker color due to filler amount is higher than binder amount	
		2	175.222	3.546	4.006		
		3	468.895	3.186	2.319		
70	30	1	40.555	3.516	4.434	Darker color due to filler amount is higher than binder amount	
		2	32.080	4.393	3.736		
		3	38.203	4.132	3.257		
80	20	1	6.277	4.335	4.299	Darker color due to filler amount is higher than binder amount	
		2	5.682	3.366	3.461		
		3	12.927	3.740	2.169		
90	10	1	0.143	4.765	5.721	Obvious colour difference that indicates filler and binder	
		2	0.100	5.279	5.890		
		3	0.085	5.641	5.716		

can be distributed evenly is contributed by the texture of sample that is less concentrated. For low viscosity ink, the printing activity becomes easier to carry out.

Apart from that, the sample texture that has low viscosity relates to the composition between the elements in the sample, which is the ratio of binder and hardener is higher than the ratio of filler. By having more binder and hardener in the sample, their microstructural behaviors are presumed to show brighter color of microstructure as they are in transparent form. Then, from 60% until 90% of filler loading, the resistivity of 60% of filler loading can be detected to have the highest total average value of

resistivity, which is 468.895 Ω/sq and the lowest is 0.1 Ω/sq from 90% of filler loading. The 90% of filler loading has the highest value of conductivity as the resistivity varies inversely with the conductivity value.

Moreover, the total average values of surface roughness are in the range of 2–5.9 μm . The highest value is 5.890 μm resulting from 90% of filler loading and the lowest value is 2.169 μm resulting from 80% of filler loading, which both are in vertical direction. With the high total average value of surface roughness, it can be presumed that the ratio of filler is higher than the ratio of binder and hardener. In addition, the filler is in the form of silver flake, which strongly makes the assumption acceptable.

For the sample with high composition of filler, its texture has high viscosity and it becomes more concentrated. Thus, during printing process, it requires extra work than usual in enabling the ink to cover the substrate evenly, which contributes to the rougher surface. Aside from having rougher surface, more filler in the sample is assumed to generate dotted spot or darker region in the microstructure as the silver nanoparticles are in dark or black color. In addition, noticeable difference of composition between filler and binder plus hardener can be presumed to be attributed by the obvious color difference in microstructure; brighter region versus dark region as displayed in 90% of filler loading.

All the results indicate that the samples with higher filler percentage has lower resistivity value and high value of surface roughness and vice versa. As for the microstructure, it is required to make the analysis for those two parameters; resistivity and surface roughness in order to find the best print resolution for optimizing the performance of printed electronics.

Conclusion

Based on the rate of conductivity for silver nanoparticles, it can be concluded that filler loadings of 10%, 20%, 30%, 40% and 50% do not have any presence of conductivity, while filler of loadings of 60%, 70%, 80% and 90% display the presence of conductivity. Thus, the decision to choose the best filler loading is merely based on the filler of loadings of 60%, 70%, 80% and 90% only. Moreover, filler loadings in the range of 60% until 90% show stable adhesion to the substrate. For the surface roughness, the lower filler loading produces smooth surface and higher filler loading shows surface irregularities. Finally, morphological analysis supports the results for both, rate of resistivity and surface roughness.

Introduction

In our day, environmental and economic concerns steered material manufacturers to produce new robust, lightweight and eco-friendly materials. Because, mass reduction by using lightweight materials decreases the fuel consumption of the vehicles which brings low CO₂ emission and low operating costs in return. In this regard, aeronautic and automobile industries work on the substitution of metallic components by composite materials. At this point, multifunctional composite materials can respond the expectations of the industry.

Polymer based composite materials can have high specific strength with the contribution of resistant fillers. In this context, epoxy is a thermoset polymer which is widely used in many different applications due to its favourable properties such as decent chemical resistance and ease in modification versatility as well as its inherent low viscosity and volatility [1]. However, epoxies generally reinforced with different reinforcements to meet the expectations. The modification of epoxy resins is generally done in different modes. First, the addition of hard particles such as glass beads or ceramics [2]. In the literature, the examples of using metal oxides such as TiO₂ and Al₂O₃ are widely seen. Nevertheless, few scientific information is available for epoxy-zirconium dioxide (zirconia) composites. Zirconia has superior properties such as high fracture toughness, high strength, outstanding wear resistance, high hardness and excellent chemical resistance [3–6]. Therefore, zirconia particles may serve as an appealing option to be used as reinforcement of epoxy to possess high tribological and mechanical properties.

Second type of modification is seen as the inclusion of thermoplastics or by the addition of elastomeric materials. Highly-crosslinked epoxy resin exhibits high brittleness because of the restriction of the plastic deformation and it has poor resistance to crack initiation and growth. Modifiers less rigid than the matrix can serve as unique toughness developers by enhancing the ductility [7]. The formation of the micro voids thanks to the rubber addition activates yielding processes because of the reduction of the local yield stress. Therefore, a significant amount of energy is dissipated within the plastic zone near the crack tip [8]. In particular, fresh scrap rubber enrich this study in terms of environmental and economic perspectives. Because, non-used vulcanized scrap rubber causes to costly landfills. Besides, in the context of landfilling, because of the impermeability and shape of scrapped tires, they keep water for a long time and this creates a habitat for mosquito larvae as well as other animals such as snakes and rodents [9,10]. These may carry infections namely malaria, cephalitis, chikungunya and dengue. Also, if these piles catch fire, it is quite onerous to extinguish them [11]. Once for all, some additives of landfilled tires such as colorants, flame retardants, stabilizers and plasticizers may leach from the bulk of the tires to the soil. Therefore, they can harm or kill some beneficial bacterial colony in the soil [12]. In consequence, in this study we open a window into the green manufacturing of the multifunctional composites by recycling of vulcanized rubbers.

The present work represents processing of recycled rubbers treated with epoxy resin to create novel composites in economic way. Main objective of this research is to determine the mechanical and tribological properties of these composites by using recycled rubber and epoxy as a matrix reinforced with zirconia. During this study, physical properties such as glass transition temperature and phase transitions are determined with dynamical mechanical analysis (DMA) and differential scanning calorimeter (DSC). Then, bending tests are realized with smooth and single edge notched beam (SENB) specimens. After that, nano indentation tests are examined to see the time dependent behaviour and wear characteristics. In addition, surface hardness is determined by means of Shore D hardness measurement and tribological characteristics are evaluated after realization of different macro and micro test technics. At the end, fracture surfaces are observed by means of scanning electron microscopy (SEM) to study the toughening and damage mechanisms.

Experimental Conditions

Materials Processing

The use of recycled rubbers inside epoxy matrix is more complicated than general belief for several reasons. Due to the previously conducted vulcanization process, cross-linked structure of rubber restrains the movement of rubber chains and limit the interaction forces between scrap rubber particles and epoxy matrix. In consequence, a reduction in the performance of final product is observed [13–15]. In this case, to enhance materials properties of the final product, devulcanization operation is recommended. According to ASTM definition, devulcanization is “a combination of depolymerization, oxidation and increased plasticity” since

during reclamation each of these processes generally occurs. *In fact*, the reverse of the vulcanization can be named as devulcanization [16]. During sulphur vulcanization, C-S and S-S bonds are formed. On the other hand, in an ideal devulcanization process, it is anticipated only C-S and S-S bonds cleavage without any main-chain degradation. Devulcanization occurs if the provided energy is higher than the link energies of monosulfidic C-S (270 kJ/mol) and polysulfidic S-S (240 kJ/mol) bonds without exceeding that of peroxide C-C (345 kJ/mol) bonds. In the frame of the current work, the energy for devulcanization is provided by microwaves and it is followed by chemical surface treatments. This combined method consists exposing recycled rubbers to microwave heating in a short time pursued by a pre-chemical treatment that is applied in practical point of view. Thereby, a good cohesion is provided at the interface between epoxy resin and rubber powders to improve the properties of the recycled rubber (SBR with a particle size varying from 30 to 130 μm .) coming from the sportive equipment. It means that they are fresh, clean and completely different from ground tire.

A new design of epoxy-based composite, reinforced with fine scrap-rubber powders and 3% Yttrium stabilized ZrO_2 is prepared in several steps:

After drying of the chemical treated rubber powders, at the final stage, devulcanized rubbers are mixed with epoxy resin powders. This mixture is used as a matrix of the new composites then, the new designed composites are manufactured by using classical powder metallurgy methods. After the mixture of the reinforcements (ZrO_2) in the matrix, milling process is carried out during 4 h.

- (1) Recycled rubbers are exposed to short microwave heating during 4 min in order to avoid degradation of the main chains [17].
- (2) Chemical treatment is applied. The procedure of the chemical treatment consists in a short silanization process followed by acrylic acid and a small amount of toluene solution to activate the surface of the rubber particles [18].
- (3) After treatment, the mixture is dried in the oven to eliminate any trace of the treatment chemicals. The mixture of epoxy resin and rubber powder is then milled 2 h to obtain a homogenous compound then heated at 80°C for 2 h and this mixture is used as matrix.
- (4) Then, the rubber-epoxy and zirconia are combined in a blender and milled for 2 h.
- (5) After blending of matrix and reinforcements, the new designed composites are manufactured by using classical powder metallurgy methods. The specimens are then manufactured by hot compacting (double uniaxial action) under a pressure of 70 MPa at a temperature of 180°C for 30 min. All of the specimens (30–50 mm in diameter) are cooled slowly.
- (6) Lastly, specimens are post-treated isothermally at 80°C for 48 h.

This procedure is illustrated in Fig. 1.

The compositions of zirconia reinforced epoxy and recycled rubber-based composites (called as ERZY I-II-III hereafter) are given in Table 1.

Fig. 1 Manufacturing of recycled rubber modified epoxy-based composites.

Table 1 Composition of the epoxy-rubber based composites

Epoxy-rubber based composition Epoxy – SBR rubber (10 phr)	ERZY I	ERZY II	ERZY III
Reinforcements (wt%)	2 ZrO ₂	4 ZrO ₂	6 ZrO ₂

Thermal Analyses and Physical Characterization

Dynamic properties, storage modulus (E') and mechanical loss angle tangent ($\tan \delta$) of the epoxy-based composites are investigated using a Dynamic Mechanical Thermal Analyser Q800 system (TA Instruments). The data are obtained at a frequency of 1 Hz, 0.1% strain in the temperature range from -80 to 200°C using a heating rate of $3^\circ\text{C}/\text{min}$ under single cantilever bending mode. The dimensions of the investigated samples are as follows: width 10 mm, length 30 mm, and the thickness 3 mm.

Differential scanning calorimeter (DSC) analyses are performed on DSC Q10N2 apparatus of TA Instruments, USA, from -80 to 400°C in air flow with a $1\text{ dm}^3/\text{min}$ flow rate and heating rate of $10^\circ\text{C}/\text{min}$.

Microstructure – Fracture Surface Analyses and Shore-D Hardness Measurements

Fracture surface damage analyses and microstructural observation have been realized by means of optical (OM) and scanning electron microscopy (SEM). SEM observation is realized on fracture surface of the tested specimens with Scope/JSM-6010LA Jeol® electron microscope.

Surface hardness measurements of the specimens are performed after post curing. Shore D hardness test measurements on the polished flat surfaces of the specimens are carried out according to ASTM D 2240 using Shore D hardness tester, (type HBD-100-0).

Fracture Toughness Measurements

There-point bending tests (3PB) have been carried out according to the ASTM D790 standards. Deflection of the specimen is measured by the crosshead position and crosshead speed is selected as $1\text{ mm}/\text{min}$. Flexural strength, strain and modulus are obtained from the test results. The test specimen is placed to the Instron 5569 bending test machine's supports and force is applied until it breaks. At least three specimens for each composition are used and standard deviation and average values are given in results article with standard deviation values.

In addition, fractural properties such as plain strain fracture toughness (K_{Ic}) and critical strain energy release rate (G_{Ic}) are investigated with single edge notched beam (SENB) specimens and the tests are realized according to ASTM D5045 standard. Notches are introduced by tapping a fresh razor blade.

Nano-Indentation Analyses by Means of Creep and Wear Tests

The time dependent behaviour is examined by means of a nano-indenter performing creep tests for three compositions manufactured to. A Berkovich indenter realized twenty indents on a 5×4 grid on each sample. The indents are spaced $50\text{ }\mu\text{m}$ along the 5-indent side and $75\text{ }\mu\text{m}$ along the 4-indent side. The load is increased at a rate of $1\text{ mN}/\text{s}$ to the max load and kept at the maximum load for 500 s then unloaded.

In addition, nano-indenter is utilized to perform relatively fast wear tests by forming scratch over the specimen. The damaged area after scratches is observed to compare the wear behaviour of the different samples. These nano wear tests are conducted by a conical tip with a 90° cone angle. Tests are run under a normal load of 20 mN applied over a linear track of 500 nm for 50 cycles.

Damage Analysis by Means of Scratch Test and 3D Optical Roughness Meter

In the current research basic idea on the tribological behaviour of the epoxy and recycled elastomer-based composites is evaluated performing scratch tests. A 3D optical surface scanner is utilized to assess damage zone after the scratch test in terms of scratch depth and average scratch roughness.

The contact between the sliding diamond indenter and the surface of the composite material during scratch test is analyzed. The normal and tangential forces on indenter are recorded. However, main focus is given to the damage area and volume. In the frame of the current research, the resistance to scratch deformation is evaluated in terms of scratch depth, surface and worn volume subsequent to scratching only under dry conditions and 50,000 and 100,000 number of cycles of wear.

Results and Discussions

Microstructure of the Composites and Hardness Measurement

In Fig. 2 two different specimens are shown in different diameters for different characterizations. They are manufactured by means of hot compaction technics.

Fig. 2 Specimens with a diameter of $d = 30\text{--}50$ mm produced from the recycled rubber modified epoxy based composites reinforced with zirconium.

Fig. 3 Microstructure of ERZY I and BES with position of the reinforcements.

Table 2 Hardness values of ERZY specimens

<i>Hardness measurement</i>	
Specimen	Shore D
ERZY I	86
ERZY II	92
ERZY III	87

General microstructures of one of the compositions are shown in **Fig. 3**. All of the compositions have shown a considerably homogenous distribution of the reinforcements in the structure. Essentially, it is seen that the adhesion of the rubber to the epoxy matrix is very successfully carried out after the chemical treatment. In the figure, an amorphous particle is observed and it is considered as a rubber particle. In addition, light coloured homogeneously distributed particles are the inclusions of epoxy matrix. Also, the gap under 100 micron of the rubber particle is commented as an extracted rubber particle during polishing process.

After microstructure observations, Shore D hardness results are given in **Table 2**.

Thermal Analysis and Physical Characterization

After all milling and material preparation processes, DSC analysis are realized on unpolymerized powder compositions and the results are given in **Fig. 4**. It is seen that curing started slightly above the room temperature and it finished around 160°C . Also, it is commented that physical and/or chemical reactions occur intensely around 330°C which are commented as degradations over 300°C . Besides, the values determined from the area of exothermic peak at a particular temperature did not vary considerably upon the addition of zirconia indicating that the presence of fillers has not affected remarkably the reaction enthalpies.

Fig. 4 DSC analysis results of ERZY specimens: Evolution of heat flow as a function of temperature.

After DSC analyses, elastic response and viscous response of the material are evaluated by determining respectively storage modulus (E') and loss modulus (E'') under dynamic loading. Then, the loss factor ($\tan \delta$) is determined by taking the proportion of loss modulus to storage modulus which is a measure of the energy lost from the material under loading at different temperatures. It shows the internal friction or mechanical damping in a viscoelastic material [19]. After acquiring the results, T_g can be determined by taking the first inflection point, or the onset of the drop-in storage modulus. Nevertheless, the simplest approach to determine T_g is taking the peak of $\tan \delta$ [20].

Fig. 5 exhibits the $\tan \delta$ and storage modulus at different temperatures for different compositions. T_g of these composites are determined around 125°C and it is seen that there is a monotonic increase T_g trend with the increasing zirconia content. Hence, it can be said that increasing amount of zirconia particles hinders the segmental polymer chain mobility. In addition, the increase in zirconia content showed a decrease in the $\tan \delta$ peak. This decrease in $\tan \delta$ indicates higher adhesion between fibers as alleged from E' curves. Because, better fiber-matrix adhesion results in low damping in the composites. Due to the fact that, after T_g these composites have quite low mechanical resistance, DMA analysis is important to determine T_g which should be considered during design process.

Three Point Bending Tests and Fracture Surface Observation

Three-Point Bending (3PB) tests have been carried out for each different type of composites.

Flexural stress is calculated during three-point bending test according to the Eq. [1]:

$$\sigma = \frac{3Pl}{2bh^2} \quad (1)$$

In this formula, l is the span length, P is the maximal bending load, b and h are the sample thickness and depth, respectively. Flexural strain, ε_f , is determined according to the Eq. [2]:

$$\varepsilon_f = \frac{6Dh}{l^2} \quad (2)$$

D is the maximum deflection at the center of the specimen.

E_B is the modulus of elasticity in bending and it is expressed with the Eq. [3] as follows;

$$E_B = \frac{l^3 m}{4bd^3} \quad (3)$$

m is the tangent of the initial straight portion of the stress-strain curve.

The mode I fracture toughness, K_{Ic} , is determined by testing of the single edge notched beam (SENB) specimens and K_{Ic} is calculated according to the Eq. [4]:

$$K_{Ic} = \frac{F}{Bw^{1/2}} f(x); x = \frac{a}{W}, 0 < \frac{a}{W} < 1 \quad (4)$$

F is the maximum force from the load-elongation trace; B is the thickness of the specimen; W is the width and " a " is the total notch length.

Fig. 5 Evolution of storage modulus and tan δ as a function of the temperature for three ERZY specimens.

Table 3 Comparison of mechanical properties of ERZY specimens

Composition name	ZrO ₂ (wt%)	Ultimate flexural stress (MPa)	Flexural modulus (GPa)	Strain at break ($\epsilon\%$)	K_{Ic} (MPa m ^{1/2})	G_{Ic} (kJ/m ²)
Matrix	–	42,13 $\pm$ 6,05	7,88 $\pm$ 0,79	0,66 $\pm$ 0,07	1,44 $\pm$ 0,12	0,66 $\pm$ 0,11
ERZY I	2	33,15 $\pm$ 3,26	3,76 $\pm$ 0,78	0,96 $\pm$ 0,06	2,45 $\pm$ 0,32	1,62 $\pm$ 0,15
ERZY II	4	32,04 $\pm$ 2,87	4,32 $\pm$ 0,63	0,92 $\pm$ 0,04	2,23 $\pm$ 0,18	1,23 $\pm$ 0,10
ERZY III	6	24,27 $\pm$ 4,13	3,96 $\pm$ 0,82	0,65 $\pm$ 0,04	1,97 $\pm$ 0,27	1,07 $\pm$ 0,13

$f(x)$ is the geometry correction factor and is expressed with the Eq. [5] as follows;

$$f(x) = 6(x)^{0.5} \left\{ \frac{[1.99 - x(1-x)(2.15 - 3.93x + 2.7x^2)]}{(1+2x)(1-x)^{1.5}} \right\} \quad (5)$$

Critical strain energy release rate (fracture energy) G_{Ic} is calculated using the expression Eq. [6] as:

$$G_{Ic} = \frac{K_{Ic}^2}{E} (\text{plane stress}) \quad (6)$$

where E is the elasticity modulus for plane stress approach examined for thin specimens.

In Table 3 flexural stress, modulus and strain values are given. From the table it is observed flexural strain is enhanced by the zirconia reinforcement. As seen in DMA analysis, loss moduli of the composites are increased. This signifies that viscoelastic characteristic of the composites is improved. Therefore, flexibility of the composites enhanced while the flexural stress and moduli reduced. The main reason for this situation is considered as the quite hard nature of the zirconia. Because, by the increase in their mass rate, they create clusters and they tend to behave as crack nucleation sites upon loading [21]. Even if they can be robust enough to improve the flexural modulus, they constitute weak points, that leads to failure when the stress is applied [6].

Fracture toughness is also examined and the results indicate an improvement in the stress intensity factor as well as fracture energy. However, fracture toughness and energy showed a downward trend by the rise in the zirconia content. This may originate because of the excessive amount of very hard particles which behaves as stress concentrators.

Fig. 6 Fracture surfaces after 3PB testing (a) ERZY I (b) ERZY II (c) ERZY III.

SEM observation is carried out on fracture surfaces after flexural tests. **Fig. 6** shows the fracture surfaces of ERZY I-II-III composites in different magnifications. As first impression, zirconia particles are homogeneously distributed over the matrix. Also, debonding of the reinforcements is not observed remarkably. This signifies the good adhesion of matrix and reinforcements. Also, rough fracture surfaces support this statement. In addition, existence of hard fillers brings with crack pinning toughening mechanism in these composites as seen in the **Fig. 6(a)** inside the red circle. Crack propagation continued until confronts a hard particle than it is stopped. Last but not least, in **Fig. 6(c)** plasticized matrix justifies the improvement in the viscoelastic behaviour.

Time Dependent Behaviour by Means of Nano-Indentation

Collected data during each indentation is used to calculate the creep compliance and the stress exponent defined in Eq. [7] [22]:

$$\varepsilon(t) = \sigma_0 J(t) \quad (7)$$

Fig. 7 Creep Compliance curves for specimens ERZY I-II-III, under 20 mN and 50 mN load.

Fig. 8 Indentation modulus for the three composites under 20 mN and 50 mN.

where σ_0 is the constant stress applied and $J(t)$ is calculated using Eq. [8]:

$$J(t) = A(t) / (1 - (\nu)) P_0 \tan \theta \quad (8)$$

In Eq. [8] $A(t)$ is the contact area, P_0 constant applied load, θ is the effective cone angle which is 70.3° for a Berkovich indenter and the Poisson's ratio (ν) is assumed to be 0.3. This approach takes into account how the contact area under the Berkovich tip alters while displacement into the surface changes.

In Eq. [9] the strain rate is given. The strain versus time behaviour during creep is characterized by a high strain rate $\dot{\epsilon} = dc/dt$ in the primary stage of creep and then in the secondary, steady state stage of creep:

$$\dot{\epsilon} = K \sigma^n \quad (9)$$

where n is the stress exponent and K is a constant. The strain rate is calculated in the software and in turn n is obtained from the log-log plot of strain rate versus stress in the secondary stage of creep.

A large scatter in the data is observed due to heterogeneous nature of the materials under consideration. The nano-indentation test is carried out over a small area/volume, and the results from a small area can be misleading. In order to overcome this, sampling number is taken as large as possible then Fig. 6 is plotted from the average values.

According to Fig. 7 creep compliance is improving until a certain point of increasing rate of zirconia then it decreases. This signifies that, at the beginning zirconia improves the viscoelastic characteristic, following trend may show differences because of the inhomogeneities in the measurement zone [23].

Fig. 9 Stress exponent for the three composites under 20 mN and 50 mN.

Fig. 10 Comparison of wear track deformation for ERZY composites.

Linear viscoelastic models can be applied to these materials to compare the results with nanoindentation. Nevertheless, these models do not consider the case of tip-specimen adhesion which may differ from experimental results.

In addition, the average indentation modulus and stress exponent values are obtained from the 20 indentations performed under 20 mN and 50 mN constant loads and they are presented in Figs. 8 and 9 with error bars showing $\pm$ one standard deviation.

First remarkable point on the Fig. 7 is thought as the wide interval of deviation values. This situation is commented as a consequence of indentation test. Because, test is performed over a very small area and when indenter tip comes across zirconia rich zone or a matrix rich area big differences are observed. Different researchers have indicated for polymers and polymer-based composites that modulus as determined by nano-indentation is higher than that determined by macroscopic tensile tests. This inequality is thought as a consequence of pile up of material around the contact impression and viscoelasticity of the polymer and polymer-based composites which are not taken into consideration during the modulus determination by the Oliver-Pharr method [24–26].

Fig. 8 indicates a similar tendency with the creep compliance values which verifies given equations.

Wear Testing by Nanoindentation

As the last step of nano-indentation technic, the indenter generated scratches over the specimen. These scratches give a practical idea regarding the wear resistance of material. One cycle is defined as a pass and return of the indenter over the track, so the total distance covered for one wear test is 0.050 m. Speed of the tip during wear tests is 50 $\mu\text{m/s}$. By examining the area of damaged

Fig. 11 Three dimensional damage traces obtained in the direction of width and length for the specimens ERZY I-II-III (respectively a,b,c) for 50 k (left) and 100 k cycles (right).

Fig. 12 Worn volume and surface subsequent to scratch tests.

Total of 10 wear tests for each specimen are performed under the two normal loads. The wear in a track is characterized as the worn area between the initial profile and the residual profile of the wear track.

Fig. 10 shows the average of the deformation on ten wear tracks. This is attributed to the inhomogeneity in the scratched zone. Also, a very small area is examined by nanoindentation technique. For this reason, macro scratch tests can present more reliable results. In this regard, macro scratch tests are performed.

Damage Analysis by Means of Scratch Test and 3D Optical Roughness Meter

As mentioned above macro scratch tests gives more explicit results. Here, after realizing three different group of macro scratch tests, a 3D optical surface scanner generated a cartography of the damaged zone. The results are presented in the **Fig. 11**.

In **Fig. 12** the surface of the damage trace after scratch calculated from roughness test results are given. There is a coherency in the results obtained from nano wear test. As expected, zirconia particles get the material more resistant to wear on the surface. This situation is supported by the worn volume values. Also, increased number of cycles did not contradict the previous statement.

The main reason for damage of the matrix and reinforced filler interfaces is thought as the high shear stress at the interfaces the interfacial shear stress. In addition, when the indenter is slipping, tangential tensile stress is caused on the surface behind the indenter, while in front of the indenter the tangential stress is compressive.

Conclusions

After manufacturing of epoxy-recycled rubber based composites, microstructure is observed with SEM. From the images, a homogeneous distribution of the reinforcements is observed. 3PB tests showed that increasing rate of zirconia has a detrimental effect on strength values. The main reason is thought as the hard nature of zirconia. Because, zirconia particles as internal defects in the microstructure and they do not allow the plastic deformation of the material. After tests, fracture surfaces are observed and homogeneous distribution of the reinforcements is seen as well as good adhesion of modifiers.

Another important point is that, modulus values obtained from nano indentation, differ from the macro test results. This is considered as a consequence of pile up of material around the contact impression and viscoelasticity of the polymer.

Also, T_g of the composites is not affected from the zirconia content which signifies that zirconia do not interfere the crosslink mechanisms of the matrix.

Finally, wear test results showed that zirconia particles are efficient against to wear thanks to its hard nature. This manifest itself in less damaged after scratch surfaces. By considering all results of the material characterizations, newly designed composites can be used in automotive and aeronautic industries in the wear resistance required applications.

Introduction

Composite materials are a combination of two or more distinct constituents including different physical and chemical properties (Khan, *et al.*, 2016), to improve the deficient characteristics of the individual materials by combining their attractive features (Corcione and Frigione, 2012). The continuous phase with a generally greater quantity is called the matrix and the discontinuous phase embedded into the matrix is called the filler/reinforcement, both of which are separated by a distinct interface. Nano-composite materials are a subset of usual composites, in which at least one dimension of the fillers is in the range of nanomaterials (1–100 nm) (Mittal, 2015) such as nanoparticles (e.g., minerals, metallic nanoparticles, carbon nanotubes (CNTs)), sheets (e.g., exfoliated clay stacks, graphene) and fibers (e.g., electrospun nanofibers). They exhibit some unique properties attributed to the presence of small-size nanofillers with a large surface area and high aspect ratio (i.e. surface area to volume ratio), leading to an improvement in the phase interactions at the interface (Rane *et al.*, 2018). Besides, due to the presence of nanometer-scale structures in their structures, the fundamental properties such as melting point, charge capacity, and magnetic properties could be controlled without altering the chemical composition (Rane *et al.*, 2018). This is because of the size-dependency of the

Fig. 1 Different types of nanocomposite structures: (a) unintercalated nanocomposite (microcomposite), (b) intercalated nanocomposite, and (c) exfoliated/delaminated nanocomposite. Reproduced from Alexandre, M., Dubois, P., 2000. Polymer-layered silicate nanocomposites: Preparation, properties and uses of a new class of materials. *Materials Science and Engineering: R Reports* 28, 1–63.

nanomaterials' properties when the particle size is less than a specific value called the "critical size" (Camargo *et al.*, 2009; Din, 2019). The interface area between the nanofillers and matrix in nanocomposites is usually an order of magnitude larger than the microcomposites that makes them a suitable alternative of conventional composites, as they require a smaller amount of fillers to achieve a desired property, which makes them much lighter in weight and cheaper than microcomposites. Besides, their size-dependency properties lead to more improvement in the thermal, chemical, mechanical, optical, magnetic, and electrical properties (Khan *et al.*, 2016).

A proper choice of matrix and nanofillers plays an important role in achieving the desired properties in nanocomposite materials. Depending on the type of the matrix material, the nanocomposites could be divided into three categories of ceramic matrix nanocomposites (CMNC), metal matrix nanocomposites (MMNC), and polymer matrix nanocomposites (PMNC) (Camargo *et al.*, 2009). Polymer matrices are usually preferred to metals and ceramics, because of their low density, high-specific stiffness (Young's modulus-to-density ratio), high-specific strength (strength-to-density ratio), and ease of fabrication of complex parts on a large-scale using traditional injection molding. However, they possess poor electrical and thermal conductivities, poor mechanical properties, and a high coefficient of thermal expansion (CTE), all of which could be improved by adding an appropriate volume fraction of nanofillers (Goyal, 2017). At a low volume fraction of nanofillers (<10 wt%), a significant enhancement can be observed in thermal, mechanical, water-resistant, and barrier properties; however, in the case of high filler contents, the toughness and optical transparency will be decreased and the melt viscosity will be increased, indicating the negative effect of high fillers' volume fraction (Goyal, 2017).

The properties of the polymer nanocomposites (PNCs) depend on a vast number of factors such as the fabrication method, type/size/shape/orientation/volume fraction/aspect ratio/distribution of the nanofillers, properties of the polymer matrix, degree of mixing of two phases, nature of the interphase developed at the matrix interface, and system morphology (Jeon and Baek, 2010; Jordan *et al.*, 2005). The homogenous distribution of nanoparticles in the polymer matrix is a critical issue to achieve enhanced properties. When the nanoparticles are not well-distributed, they tend to agglomerate to each other which deteriorates the desired properties obtained by nanocomposites. Depending on the degree of nano-sized layer dispersion, three types of PNC morphologies could be obtained (Alexandre and Dubois, 2000): unintercalated/conventional/PNCs, intercalated/flocculated PNCs, and exfoliated/delaminated PNCs.

Unintercalated Polymer Nanocomposite (Microcomposite). When the polymer molecules are unable to penetrate and intercalate between the nanolayers, the phases are separated in the composite structure (Fig. 1a). The d-spacing of the layer structures is nearly identical to their pristine state and consequently, the properties of the obtained nanocomposite are in the same range as the microcomposites (Müller *et al.*, 2017).

Intercalated Polymer Nanocomposite. When the extended polymer chains can intercalate and sandwich in between the nanolayers without disturbing their ordered arrangement, a well-ordered multilayer morphology with alternating intercalated layers of polymer and clay will be formed (Fig. 1b). Consequently, the interlayer d-spacing is expanded, but only to a limited extent of 20–80 Å (Alexandre and Dubois, 2000).

Exfoliated/Delaminated Polymer Nanocomposite. When the separated individual nanolayers are uniformly dispersed in the polymer matrix, an exfoliated structure will be formed (Fig. 1c) in which the surface area between the matrix and nanofillers is larger than the case of unintercalated and intercalated polymers, and consequently, the maximum reinforcement will occur (Bhattacharya *et al.*, 2007). The d-spacing between the layers is significantly expanded up to 10 nm or more, above which the interaction forces between the layer structures diminish. Achieving an exfoliated structure of the PNCs is the ultimate goal of most researchers because of obtaining the maximum improvement in the nanocomposite properties. The exfoliated nanocomposites could be subdivided into three categories of ordered, disordered, and partial exfoliated PNCs, depending on the relative change in layer spacing and orientation (Alexandre and Dubois, 2000). When the ordered and parallel arrangement of the nanolayers is preserved

during the dispersion in the polymer matrix, a homogeneous morphology with individual separated layers is formed which is called the ordered exfoliated nanocomposite, while in the case of disordered exfoliation, the ordered arrangement of the nanolayers is completely disrupted to form a homogeneous and random dispersion of individual nanolayers in the polymer matrix. The partially exfoliated nanocomposites behave as an intermediate of the intercalated and exfoliated structure since it is associated with dispersed exfoliated layers and small stacks of intercalated layers, making its morphology as a middle of the case of exfoliation and intercalation (Liu *et al.*, 2006). It should be mentioned that exfoliation requires high shear and high temperature which is a great challenge for the materials.

Depending on the type of PNC morphology, different physical and mechanical properties will be obtained (Liu *et al.*, 2006). To reach an intercalated or exfoliated structure, it is required sometimes to modify the surface of the nanofillers with the chemical groups that are compatible with the polymer, to minimize or even avoid the agglomeration of nanoparticles which has a detrimental influence on the nanocomposite structure and properties (Goyal, 2017).

PNCs have a wide range of applications in various fields such as food packaging, aerospace industries, automobile sectors, oil and gas pipelines, and bone repairs, etc. The purpose of this article is to first describe different types of nanocomposites with a focus on the PNCs followed by a detailed explanation of their characterization techniques (structural analysis, thermal properties, mechanical properties, and electrical properties) and their industrial applications (biomedical and tissue engineering applications, energy-related applications, corrosion protection applications, ballistic, aerospace, and automobile applications, ultraviolet (UV) protection applications, sensors applications, smart PNCs applications, adhesive applications, and flame retardant PNCs).

Different Types of Polymer Nanocomposites

As it was mentioned before, the nanocomposite materials can be classified into three categories of CMNCs, MMNCs, and PMNCs, each of them is explained below (Khan *et al.*, 2016).

Ceramic Matrix Nanocomposites (CMNC)

Ceramic is a brittle material that can be easily fractured under a crack propagation. The incorporation of a ductile phase in the ceramic matrix to form a ceramic nanocomposite improves its mechanical properties such as hardness and fracture toughness, attributed to the interactions between the matrix and reinforcements. To deeply understand the structure-property relationship in the CMNC, the ratio of surface area to the volume of the reinforcement materials is a key factor. Some of the common methods of fabricating the CMNCs are conventional powder method, polymer precursor route, spray pyrolysis, vapor techniques (Chemical Vapor Deposition (CVD) and Physical Vapor Deposition (PVD)), and chemical methods such as the sol-gel process, colloidal and precipitation approaches, and template synthesis (Camargo *et al.*, 2009; Liu *et al.*, 2004; Thompson *et al.*, 2003). Some of the common CMNCs are $\text{Al}_2\text{O}_3/\text{SiC}$, $\text{Al}_2\text{O}_3/\text{SiO}_2$, $\text{TiO}_2/\text{Al}_2\text{O}_3$, $\text{Al}_2\text{O}_3/\text{CNT}$, $\text{TiO}_2/\text{Fe}_2\text{O}_3$, $\text{Fe}_3\text{O}_4/\text{CNT}$, SiO_2/Ni , SiO_2/CNT , ZnO/Co , $\text{MgAl}_2\text{O}_4/\text{CNT}$, and MgO/CNT (Parameswaranpillai *et al.*, 2016).

Metal Matrix Nanocomposites (MMNC)

The reinforcement of nanoparticles in the ductile metal/alloy matrix forms MMNCs with entirely different physical, chemical, and mechanical properties compared to the individual metals and nanoparticles. A significant improvement in the mechanical properties of the metal nanocomposites is because of the interactions between the nanoparticles and dislocations when the nanoparticles act as a barrier in dislocation movements. From the common fabrication methods of MMNCs, it can be referred to the spray pyrolysis, liquid metal infiltration, vapor techniques (CVD and PVD), rapid solidification, electrodeposition, and chemical techniques such as colloidal and sol-gel methods (Camargo *et al.*, 2009). Some examples of the common MMNCs are $\text{Fe}/\text{Al}_2\text{O}_3$, $\text{Ni}/\text{Al}_2\text{O}_3$, Fe/MgO , Al/CNT , and Mg/CNT .

Polymer Matrix Nanocomposites (PMNC)

PMNCs involve the addition of one-dimensional (such as nanotubes and fibers), two-dimensional (such as layered materials), and three-dimensional (such as spherical particles) nanofillers in the polymer matrix. The addition of a low volume fraction of nanofillers in the polymer matrix leads to outstanding properties such as barrier resistance, flame retardancy, wear resistance, easy production, high elastic stiffness and strength, lightweight, ductile nature, and generally excellent magnetic, electrical, mechanical, and optical properties, although, they possess lower modulus and strength compared to the case of ceramic and metal nanocomposites. Some of the common fabrication methods of PMNCs are in-situ polymerization, in-situ intercalative polymerization, intercalation of polymer/pre-polymer from solution, direct mixing of polymer and fillers (particulates), mixing filler materials during electrospinning, melt intercalation, melt mixing, template synthesis, and sol-gel process. Some examples of the common PMNCs are thermoplastic polymer/layered silicates, thermoset polymer/layered silicates, polyester/ TiO_2 , polymer/ CNT , and polymer/layered double hydroxides.

The major component in a PMNC is the polymer itself. A vast variety of polymers is used in the preparation of PMNCs, three common types of them are thermoplastics, thermosets, and elastomers. The main difference between the thermoplastic and thermoset polymers is their different behavior against heating attributed to the difference in their molecular structure. Thermoplastic polymers soften to a mobile and flowable state under heating and can be shaped into a useful object and harden/solidify under cooling, while holding their shape (Peters, 2014). Hence, they could be remolded and recycled without affecting the properties. The curing process is completely reversible since no cross-linking takes place. In contrast, the thermoset polymers do not soft or melt under heating and retain their strength and shape, but breakdown chemically at high temperatures. They exhibit elasticity and chemical resistance and withstand elevated temperatures from ambient to above 450 °F, without loss of structural integrity. The curing process is irreversible, attributed to the cross-linking of polymers together. Thermoset polymers are generally rigid and brittle compared to thermoplastics, possessing improved mechanical properties, high chemical and heat resistance properties. The third type of polymers is elastomers that are elastic or rubberlike with high elongation and flexibility against breaking and can be classified into thermoset elastomers and thermoplastic elastomers that the first type is not melted when heated while the second one is melted. The thermoset-based nanocomposites are generally the most common type used in many applications; however, the thermoplastic-based nanocomposites have recently gained the attraction of many researchers in both industry and academia (Koo, 2006), including the automotive and packaging area (Lampman, 2003).

The reinforcing materials in the PNC structures can be classified based on their dimension into three categories of one, two, and three-dimensional materials. The three-dimensional nanofillers, also called isodimensional nanoparticles, contain three dimensions in the nano-scales, some examples are spherical silica, metal particles, and semiconductor nanoclusters (Herron and Thorn, 1998). In the two-dimensional nanofillers, two dimensions are on the nanometer scale and the other on a larger scale, some examples are CNTs and cellulose whiskers. Carbon nanofibers, ranging from disordered “bamboo-like” to highly ordered “cup stacked” graphite structures with a diameter ranging from 50 to 200 nm, are a kind of two-dimensional nanofillers employing in a variety of polymer matrix compounds, including both thermoset polymers (such as epoxy, polyimide, and phenolic) and thermoplastic polymers (such as polypropylene, polystyrene, poly(methyl methacrylate)) PMMA, Nylon 12, and PEEK (Sandler *et al.*, 2003). The one-dimensional nanofillers with the one dimension in the nanometer range and the others in the larger scale, and the nanocomposite containing these nanofillers are called polymer-layered nanocomposite. Polymer layered silica nanocomposites are a type of one-dimensional nanocomposites with a significant improvement in their properties such as possessing high moduli, high strength and heat resistance, low flammability, low gas permeability, and high biodegradability. The ability of the layered silicate to disperse into the individual layers along with the ability of fine-tuning their surface chemistry lead to the formation of strong interactions between the nanolayers and the polymer matrix, forming an intercalated or exfoliated nanocomposite.

A brief description of the different types of nanocomposites, their properties, synthesized methods, and common examples are given in Table 1.

Characterization and Analysis of Polymer Nanocomposites

After preparation of the PNCs by a proper method, the obtained material should be characterized to determine the degree of nanoparticles' dispersion in the polymer matrix and to analyze the thermal, mechanical, and electrical properties to find out whether it is desired for our purpose or not. Therefore, the nanocomposite characterization is divided into structure analysis, using a variety of microscopic and spectroscopic techniques, and property measurement (i.e., thermal, mechanical, electrical), depending on the individual applications (Koo, 2006). The main challenge in characterizing the nanostructures is the dependency of their physical properties on the size and shape. The surface modification of the small size (i.e., diameter and length) nanostructures is rather difficult and also it is not possible to apply the common well-established techniques for their characterization. Consequently, some specialized techniques are required for identifying and analyzing individual nanostructures and quantifying their properties. In what follows, the methods of PNC characterization are described based on three categories of structural/morphological characterization, thermal characterization, and mechanical characterization.

Structural and Morphological Characterization

The methods of characterizing the structure of PNCs can be generally divided into four categories of microscopic techniques, spectroscopic techniques, scattering techniques, and chromatography, each of which has several subdivisions which are described in detail below.

Microscopic techniques

The microscopic techniques usually provide a suitable picture of nanocomposite morphology that like a microscope, could give an image of the structure.

Optical microscopy

Optical microscopy is usually a useful tool for characterizing the microcomposite structures in the cases of very thin samples with a transparent matrix. So, it is not a suitable tool for characterization of the nanosize materials.

Table 1 Properties, synthesized methods, and common examples of ceramic, metal, and polymer nanocomposites

<i>Types with Features</i>	<i>Nanocomposites</i>	<i>Synthesis method</i>
1. Ceramic Advantages: Good wear resistance High thermal and chemical stability Disadvantages: Brittle Low toughness	Enhanced mechanical properties including fracture toughness, stiffness, and strength	Conventional powder method Polymer precursor route Spray pyrolysis Vapor techniques (CVD and PVD) Chemical methods (sol-gel process, colloidal and precipitation approaches, template synthesis)
2. Metal Advantages: Electrical and heat conductive Ductile toughness with high strength and modulus Disadvantages: Highly corrosive	Wear and chemical resistance High electrical and thermal stability High strength in shear/compression processes	Spray pyrolysis Liquid metal infiltration Rapid solidification Vapor techniques (CVD and PVD) Electrodeposition, Chemical methods (colloidal and sol-gel processes)
3. Polymer Advantages: Easy production process Lightweight Ductile Disadvantages: Low strength and modulus	Mechanical strength Enhanced magnetic, electronic, optical, and catalytic properties Flame retardancy Low gas permeability high biodegradability	In-situ intercalative polymerization Intercalation of polymer/pre-polymer from solution Direct mixing of polymer and fillers Melt intercalation Template synthesis Sol-gel process

Electron microscopy

In this method, the images are obtained by using high-energy electrons with a wavelength ($0.025\text{--}0.1\text{ \AA}$) much smaller than that of the light, allowing for imaging the small objects in the nanometer scale. The electron interactions with the samples give detailed information on their structure. This method is based on the wave-particle duality of electrons and it is widely used when a much larger magnification than that of light microscopic techniques is required, as the particle size is smaller than the wavelength of the visual light (Bhattacharya *et al.*, 2007). The three main electron microscopic techniques for characterizing the nanocomposite morphology are scanning electron microscopy (SEM), transmission electron microscopy (TEM), and atomic force microscopy (AFM).

Scanning electron microscopy (SEM)

In this method, a focused electron beam is produced by an electron gun to scans over a specimen with an electrically conductive surface. In the case of electrical isolator surfaces like most of the polymeric materials, the surface of the sample should be coated with a layer of a conductive material such as gold or carbon, or the environment of the sample should be conductive. As a result of the interaction between the electron beams and the atoms of the specimen surface, various signals will be produced and detected by a detector and the scanned image of the surface will be obtained by reproducing the varying intensity of the detected signals on a screen. SEM method is one of the most frequently used techniques of nanostructured surface characterizations with a high resolution of $1\text{--}5\text{ nm}$ and a large depth of field which makes the images appear three-dimensional (Oksman and Moon, 2014). The main limitation of this method is the surface scanning of the specimen without characterizing the inner parts which can be partially addressed by using cold temperature fracture or ultra-microtoming.

Transmission electron microscopy (TEM)

In this method, the high energy electrons are emitted from an electron gun and transmitted through an ultrathin section of the specimen. Two or more condenser lenses are inserted below the gun to demagnify the emitted beam and control its diameter when hitting the specimen that is held inside an objective lens just below the condenser lenses. The objective lens in TEM is critical as it determines the limit of image resolution. As the electron beam hits the specimen, an image will be formed as a result of electron scattering. In bright-field (BF) imaging mode, for instance, the image is formed by the unscattered electrons; the thicker or higher density regions of the specimen strongly scatter electrons and will appear darker in the image since the highly scattered electrons are stopped by the objective aperture (Oksman and Moon, 2014). The TEM method provides direct visual information of the morphology, molecular arrangement, and spatial distribution of the phases along with detecting structural defects within the selected area of the sample. The better resolution of the TEM method (0.2 nm) compared to the SEM (2 nm) as a result of higher electron energy, along with providing the internal information of the specimen by TEM compared to the surface information by SEM, make the TEM method more applicable than SEM (Koo, 2006). In the case of PNCs, TEM is the most suitable microscopy

method to provide direct imaging of the extremely small size nanoparticles along with determining the nanofillers distribution and dispersion (including uniformity and non-uniformity) as it analyzes the through-thickness of the material. By applying today's TEM devices, the chemistry of a single nanocrystal can be directly identified because of providing the atomic resolution lattice images and chemical information at a spatial resolution of 1 nm. Some of the main limitations of the TEM method are the high cost of analytical instruments, the difficult process of sample preparation, the inability of scanning heterogeneous samples, and the inability of detecting the intercalated and exfoliated nanocomposites, attributed to the inability of measuring the d-spacing between the nanolayers (Reifarth *et al.*, 2018). The sample preparation is critical to obtain a good resolution TEM image. Some of the basic requirements are that the sample should be thin enough to be transparent to the electron beam and also it should be clean without any damage or contamination. The common methods of sample preparation are ion milling (for all kinds of materials), electropolishing (for conductive materials), and crushing powder (for all materials but neglecting the detail of microstructural). The sample is usually prepared by ultra-microtoming at room temperature, when the polymer T_g is higher than the room temperature and at low temperature, when the polymer T_g is lower than the room temperature (Morgan and Gilman, 2003).

Atomic force microscopy (AFM)

In this method, by scanning the AFM probe with a typical curvature radius of 10 nm via operating modes of contact or intermittent-contact over the composite surface, the interactive force between the atoms of the probe and those of the specimen is measured and the interaction response is monitored, resulting in a topography image. The forces applied to the specimen are typically in the order of 10^{-9} N, which is small enough, ensuring no damage to the specimen (Bhattacharya *et al.*, 2007). By maintaining the feedback on the amplitude of the probe variation in the intermittent-contact mode, the nanoparticle distribution within the PNC can be obtained using phase imaging that records the phase lag (i.e., delay) of the cantilever oscillation, relative to the signal sent to the cantilever's piezo driver. The phase lag is sensitive to variations in material properties such as adhesion, viscoelasticity, etc., and a contrast will be created between the different material components within nanocomposites. In the phase images, the harder phase appears lighter due to the higher phase offset, whereas the softer phase appears darker. The edges can be also highlighted via phase imaging, providing a clearer observation of fine features such as grain edges. The AFM method is a relatively new technique in characterizing the nanometer-scale features of the surface chemistry, especially in the case of nanocomposites with an atomic resolution of 0.2–0.5 nm (Braga and Ricci, 2004; Bandyopadhyay *et al.*, 2008). Considering the nature of the AFM method as a surface characterizing technique, it is necessary to image multiple sections through the thickness of the nanocomposite to characterize the nanoparticle distribution through the thickness (Marinello *et al.*, 2019; Kumar *et al.*, 2014). Despite the SEM and TEM methods which are only applicable for conductive samples, the AFM can image both conductive and nonconductive materials usually under atmospheric conditions (Oksman and Moon, 2014).

Spectroscopic techniques

To analyze the chemical structure of macromolecular materials such as functional groups, structural conformation, and component concentrations, spectroscopic techniques are used. These methods involve the interaction of the sample molecules with electromagnetic (EM) radiation and an image will be obtained by monitoring the changes in energy states of molecules in response to EM radiation as the atom/molecule's energy will exceed from an initial state to a higher level by adsorbing energy.

Fourier transform infrared (FTIR) spectroscopy

In this method, a beam of infrared (IR) radiation emitted from a glowing black-body source is passed through the specimen. By exposing the specimen's molecules to the IR radiation, they absorb some specific frequencies of the energy as the unique characteristic of the sample, and the unabsorbed frequencies will be transmitted and recorded by a detector, enabling the identification of the absorbed ones (Berthomieu and Hienerwadel, 2009; Marley *et al.*, 2001). The energy of the specimen's molecules will be risen to a higher level by adsorbing the IR energies, resulting in their vibration at greater amplitudes, depending on the atomic weight and the force constant of the atom bound to its environment. These vibrational frequencies correspond to the region within the IR spectrum and the unknown molecules will be then identified by matching the absorption wavelength/frequency to those already known (Li *et al.*, 2006; Suhail *et al.*, 2019).

Nuclear magnetic resonance (NMR)

In this method, the specimen is exposed to a magnetic field, hitting by radio waves. The atoms' nucleus of a sample is in spinning or resonance motion, inducing a magnetic moment that is aligned randomly, in the absence of a magnetic field and regularly, in the presence of it. By exposing the positively charged nucleus to the radio waves of the magnetic field, the magnetic field of the nucleus will resonate (Papon *et al.*, 2012). The response of the atomic nucleus to the magnetic field, which is due to the shielding of a particular nucleus by the neighboring nuclei, is measured in the form of a spectrum (Munoz and Greenbaum, 2018; Drzeżdżon *et al.*, 2019).

Ultraviolet spectroscopy

In this method, light is passed through a sample at a specific wavelength (200–400 nm) in the UV or visible spectrum. The molecules containing bonding and non-bonding electrons can absorb energy in the form of UV/visible light to excite these electrons between the energy levels, corresponding to the molecular orbitals. In particular, the transitions involving p orbitals and

lone pairs (n = non-bonding) are more important (Zhang *et al.*, 2013; Munk and Aminabhavi, 1989). The UV-visible spectroscopy is mostly used for identifying the conjugated systems that tend to have a stronger absorption. The shape and absorbance of the spectra can be measured with good precision. The measurement of absorbance provides useful information for calculating the concentration of macromolecules; however, it is not useful in obtaining structural information (Li *et al.*, 2006).

Energy-dispersive X-ray spectroscopy (EDS/EDX/EDXS)

When a sample is exposed to the SEM electron beam, electrons are ejected from the atoms of the sample surface. The resulting electron holes are filled by electrons from a higher state, and an x-ray is emitted to balance the energy difference between the two electrons' state. In the EDS technique, these emitted x-rays are detected and their relative abundance is measured versus the energy, to determine the elemental composition of the sample. The spectrum of EDS microanalysis contains both semi-qualitative and semi-quantitative information. The emitted X-rays and their intensity distribution are a characterization of the element type and atom densities, respectively (Son *et al.*, 2020). Generally, the EDS is an analytical technique used for the elemental analysis or chemical characterization of a sample since each element has a unique atomic structure allowing a unique set of peaks on its EM emission spectrum (Hosseini *et al.*, 2015; Schmidt *et al.*, 2019).

Scattering techniques

The scattering methods are used to analyze the morphology and structural evolutions of micro/nanocomposite materials. The three main scattering techniques used in PNCs are X-ray scattering (XRS) (wavelength between 0.01 and 0.2 nm), light scattering (wavelength between 350 and 700 nm), and neutron scattering (wavelength between 0.1 and 1 nm), depending on the electron densities, optical densities/refractive indices, and nature of the scattering nucleus, respectively. The main difference between these methods is the length scale probed, relating to the wavelengths of the scattering beam. The similar and small wavelength of X-ray and neutron scattering indicates their applicability for the same structure size, while large structures could be investigated via light scattering because of their larger wavelength (Chen *et al.*, 2018).

X-ray scattering

The XRS techniques can differentiate between the crystalline and semi-crystalline materials and consequently, making them useful in analyzing the solid materials. Depending on the magnitude of the angle deviation from the direct beam, the XRS can be divided into two subcategories of small-angle (SAX) and wide-angle (WAX) regions. The exact difference between the region areas of SAX and WAX is still ambiguous. Alexander in 1969 considered any scattered beam larger than 2° or 3° as a WAX region, while other researchers such as Morgan and Gilman in 2003 classified the angles greater than 1° as a WAX region (García-Gutiérrez *et al.*, 2007).

Wide-angle X-ray scattering (WAX/WAXS)

The WAX method is a method of investigating the partially ordered materials. The crystalline structure of the PNCs along with the degree of nanofillers dispersion in the polymer matrices could be characterized via this method by measuring the d-spacing between the ordered crystalline layers of the nanolayers (Chen *et al.*, 2018). The d-spacing is measured based on Bragg's law with the following equation:

$$\sin\theta = \frac{n\lambda}{2d} \quad (1)$$

Where d is the spacing between the interlayers, λ is the x-ray wavelength, n is a positive integer, and θ is the angle of incidence. The intensity of the diffracted x-ray is measured as a function of the diffraction angle 2θ and the specimen's orientation. The specimen's crystalline phases and its structural properties could be measured using the diffraction pattern (Bhattacharya *et al.*, 2007). An initial assessment of the structure and morphology of the PNCs can be made by observing any changes in the d-spacing. One of the main advantages of the WAX method compared to the electron microscopy methods is that it does not require any sample preparation and consequently, it is a non-destructive method, indicating the wide usage of this technique in materials characterization (Bishnoi *et al.*, 2017).

Small-angle X-ray scattering (SAX/SAXS)

In this method, the sample is irradiated by a well-defined, monochromatic x-ray beam with the purpose of structural characterization of solid and fluid materials in the nanometer range (0.5–50 nm). The very low scattering angles of the SAX method, make it possible to obtain the structural information of the nonhomogeneous specimens from the intensity distribution of the scattered beam (Demchenko and Riabov, 2017). Both monodisperse and polydisperse systems can be analyzed via the SAX method. In the monodisperse systems, the size, shape, and internal structure of the particles can be determined, while in the polydisperse systems, a size distribution can be only obtained when the shape and internal structure of the particles are the same (Cser and Bhattacharya, 2003; Sakurai, 2017). SAX method can be used in structural characterization of different materials such as suspended nanopowders, polymer films and fibers, catalyst surface per volume, microemulsions, and liquid crystals (Baeza *et al.*, 2016).

X-ray diffraction (XRD)

The diffraction process is only possible in cases where the wavelength of the wave motion is in the same order of magnitude of the repeat distance between the scattering centers. XRD is a convenient and rapid method for initial characterization of

nanocomposites structure and morphology, by monitoring the intensity, position, and shape of the basal reflections from the distributed nanofillers (Demchenko *et al.*, 2017). The distance between the interlayers could be determined from this method as an indication of the success or failure of the ion-exchange process during the nanofiller modification or the intercalation/penetration of the polymer chains. It is also possible to identify the non-intercalated, intercalated, and exfoliated structures via the XRD method, when there is no change in peak, an increase in peak, and no peak, respectively (Abhilash *et al.*, 2016).

Light scattering

This technique involves the light scattering through dilute solutions, as a widely used technique in polymer science to determine the molecular weight, second virial coefficient as an intermolecular interaction parameter, and the radius of gyration of high molecular-weight polymers (Yadav *et al.*, 2017).

Small-angle light scattering (SALS)

By using the SALS method, it is possible to determine the relationship between the structure and properties of the PNC in both solid and melt phases. The structural evolution of the nanocomposites could be investigated by determining the shape and size of the crystalline nanostructures (Shibayama *et al.*, 2005; Oberdisse *et al.*, 2017; Jouault and Jestin, 2016).

Neutron scattering

Small-angle neutron scattering (SANS)

The underlying principles of the SANS method are similar to the SAXS and SALS techniques, except that of the wavelength, and consequently, the length scale is the probing parameter. In this method, a neutron approaches an atomic nucleus the nuclear forces repel it, resulting in a scattered neutron beam. The structural evaluation of the nanocomposite samples will be then possible as the scattered neutron interferes with other waves.

Chromatography

Gel permeation chromatography (GPC)

The GPC method is conducted on polymer solutions, resulting in the hydrodynamic volume of the dissolved polymer. In this method, the polymer is first dissolved in a suitable solvent and the obtained solution is injected into a porous gelled column with a gelled material such as cross-linked polystyrene, dextran, polyacrylamide, or even styrene-divinylbenzene copolymer (Styragel) (Bhattacharya *et al.*, 2007; Bhattacharya, 2016). To determine the polymer molecular weight, the porosity of the column should be varied. Different types of average molecular weights can be determined by the GPC technique including the weight average molecular weight (M_w) (based on the concept of the highest "concentration" of molecular weights), number average molecular weight (M_n) (the ratio of total molecular weights of all samples and total number of polymer molecules, and the viscosity average molecular weights) (M_v) (based on the viscosity) (Yei *et al.*, 2004). Besides the determination of molecular weight, it is also possible to specify the polydispersity index (PI), and the branching index. The PI, calculated from the ratio of M_w and M_n , is an indication of the molecular weight distribution in the polymer. A PI of 1 corresponds to a monodisperse material, whereas higher values correspond to a wider distribution of the molecular weights of the macromolecules. The usage of suitable filters before the test is necessary for the GPC analysis of filled materials, such as PNCs, where the clay will not dissolve in the organic solvent (Zhen and Zheng, 2016).

Thermal Properties

Characterization of the thermal properties involves the techniques in which a property of a specimen is continuously measured through a pre-determined temperature profile to analyze the changes in the heat content (enthalpy) or the sample's specific heat (Kumar *et al.*, 2019).

Differential scanning calorimeter (DSC)

In this method, as one of the most common thermal analysis techniques for nanocomposite materials, different parameters could be measured during the thermal heating such as glass transition temperature (T_g), melting, crystallization, and curing (Lionetto and Maffezzoli, 2008). Considering T_g as the Brownian motion of the polymer chains during the transition from the glassy to the rubbery state and the relaxation of dipoles associated with it, the presence of nanofillers in the PNC structures leads to the enhancement of T_g that can be measured via the DSC technique. The T_g enhancement is attributed to the encapsulation of the intercalated polymers in the nanofillers galleries, preventing the partial movement of the polymer chains (Chattopadhyay and Webster, 2009; Kazakova *et al.*, 2018). By applying thermal energy, the enhancement of enthalpy and specific heat of the sample can be also measured by the DSC technique; regarding the point that the changes in specific heat are slow at a specific state, while changes sharply during a state alteration, inducing some physical or chemical changes in the sample (such as melting or decomposition) accompanied by a change in enthalpy in the form of the latent heat of fusion, the heat of reaction, or others (Rahman *et al.*, 2017).

Thermogravimetric analysis (TGA)

In this method, the sample is continuously weighted in a controlled atmosphere (e.g., air or nitrogen) as the temperature is linearly increased. The filler content of a PNC material along with its thermal stability improvement during temperature changes can be quantitatively measured via the TGA method. The improvement of thermal stability, which means that the thermal degradation occurs at a higher temperature, is attributed to the formation of a char that hinders the out-diffusion of the volatile decomposition products due to the permeability reduction and is usually observed in exfoliated or intercalated nanocomposites (Leszczyńska *et al.*, 2007). The improvement in thermal stability of the nanocomposites is somewhat dependent on the amount of filler content; at low filler content of about 1 wt%, the amount of exfoliated nanofillers is not enough to enhance the thermal stability through char formation (Alexandre and Dubois, 2000); at intermediate filler content of about 2–4 wt%, more exfoliated nanofiller is formed and the thermal stability is improved attributed to the easy and effective formation of char; and finally, at high filler content of up to 10 wt%, the intercalated structure is the dominant population and the high thermal stability is not maintained due to the different morphology of the nanocomposite even at high quantity formation of char (Taha, 2017). Generally, the most important factors with a critical role in the thermal degradation of PNCs are the chemical nature of the polymers, the type of nanofillers, and their modification route (Kausar, 2018; Loganathan *et al.*, 2017).

Cone calorimeter (CC)

In this method, the small sample of material is burned in the device to evaluate the sample reaction to the fire via direct or indirect measuring of various parameters such as time to ignition, ignitability, rate of surface flame spread, heat release rate per unit area, cumulative heat release, mass loss rate, total mass loss, effective heat of combustion, combustion products, smoke evolution, smoke obscuration, and evolution of toxic gases (Shen *et al.*, 2017; Hanna *et al.*, 2018; Zanetti *et al.*, 2002).

Mass loss calorimeter (MLC)

The MLC method only determines the mass loss rate and ignitability at a specific heat flux condition and is a suitable replacement for the cone heater cell assembly in the CC. As a stand-alone instrument, the MLC could be considered as a quality control tool, containing two parts of the cone heater assembly and the control assembly. The combustion products and their toxicity can be also measured via this system. The approximate value of the heat release rate can be estimated from the mass loss rate data if the effective heat of combustion (ratio of heat release rate and mass loss rate) is known (Koo, 2006).

Mechanical Properties

The mechanical properties of PNCs are strongly dependent on the type and properties of matrix and fillers, filler distribution in the matrix, interfacial bonding and interaction between filler and matrix, the aspect ratio of filler, and the fabrication method (Krishnaiah *et al.*, 2017). As noted earlier, the surface modification of the nanofillers could strongly promote the filler distribution and their interfacial adhesion to the matrix material. The methods of mechanical analysis measure the tensile strength, tensile modulus, and elongation, which are a measure of the material's strength under the tensile loading, material's resistance to the deformation, and material's stretching/deformation before the break, respectively (Shah *et al.*, 2016). A failure in the composite structure usually initiates with a crack formation and by adding nanofillers with a smaller size than the crack length, the toughness and strength of the sample will be improved, as the nanoparticles fill the cracks (Sun *et al.*, 2018). Besides, the aspect ratio could be increased via the addition of a high volume ratio of nanofillers to the polymer matrix, leading to an increment in Young's modulus and yield strength, although above an optimum concentration the nanofillers aggregation induce a negative effect on the mechanical properties of the nanocomposites (Bhattacharya, 2016).

Dynamic mechanical thermal analysis (DMTA)

The dynamic mechanical properties of PNCs depend on the nanoparticle orientation, polymer morphology, and strength of interphase interactions of the nanofillers, all of which can be improved by the introduction of macromolecular compatibilizers (Candan *et al.*, 2016). By the DMTA technique, it is possible to measure the storage modulus (E') and loss modulus (E'') as the two material's ability in returning/storing the mechanical energy, and in dissipating energy, respectively, as a function of temperature (Jayanarayanan *et al.*, 2017). Some useful information about the nanofillers' orientation, exfoliation, and interphase interactions could be also measured indirectly (Lionetto and Maffezzoli, 2009).

Thermomechanical analysis (TMA)

The TMA method is used to measure the expansion/contraction of cross-linked or filler materials and the coefficient of thermal expansion of nanocomposite materials (Fu *et al.*, 2008; Krump *et al.*, 2006). The lower value of CTE is an indication of better thermal properties of nanocomposites and the degree of CTE reduction depends on the nanoparticle rigidity, particle dispersion/distribution, stress transfer to nanolayers, and retardation of chain segmental movement through the incorporation of modified nanolayers (Burgaz, 2016).

Dynamic mechanical analysis (DMA)

In this method, an oscillating force is applied to the sample at a specific temperature, resulting in a deformation that is measured to determine the sample stiffness, sample storage modulus, and viscoelasticity. Furthermore, the damping properties of the material can be determined by measuring the time lag in the displacement compared to the applied force (Liu *et al.*, 2003; Chauhan *et al.*, 2018).

Electrical Properties

The electrical properties of common polymers are usually low than 10^{-14} S/m, indicating their inability in conducting electricity. These properties could be enhanced by introducing conductive nanoparticles/nanotube/fibers into the polymer matrices in the form of nanocomposite structure (Mutiso and Winey, 2015). The degree of electrical conductivity of the obtained nanocomposite is strongly dependent on the volume fraction of conductive fillers. In the case of low-filler loadings, the conductivity of the nanocomposite is nearly close to that of the polymer matrix. Increasing the filler loading leads to a slight increment in the electrical conductivity until reaching a critical volume fraction, at/above which a sharp increase is observed. Just above a percolation threshold, the nanofillers begin to form some three-dimensional conductive networks which assist in electrons flow from one end to another end of the sample (Allaoui *et al.*, 2002). Depending on the shape, size, and aspect ratio of the nanofillers, the onset of percolation and the required nanofillers concentration may be different (Hashemi and Weng, 2016). As an instance, the required particle concentration for the percolation threshold for fiber is several orders of magnitude less than the case of spherical particles, indicating the inverse relation between the percolation threshold and the aspect ratio of nanotube/nanofibers (Bandaru, 2007). Above the percolation, a sharp increase of several orders of magnitude is observed in the electrical conductivity. A decrease in the aspect ratio of the nanofillers in a given nanocomposite due to their poor dispersion or agglomeration results in a significant difference between the percolation threshold and the highest obtained electrical conductivity (Otaegi *et al.*, 2019). Generally, the percolation threshold is dependent on the chemical, physical, and geometrical parameters such as the type of polymer matrix (amorphous or semicrystalline) and nanofillers, surface treatment of nanofillers, fabrication method, spatial distribution/dispersion, and aspect ratio (Tschöpe and Birringer, 2001). Despite the positive effect of chemical functionalization of the nanofillers on their better dispersibility and improvement of their mechanical properties by forming stronger bonds between the matrix and the nanotube, it usually reduces the electrical conductivity of the nanocomposites, attributed to their tendency of scattering electrons instead of transporting. Moreover, the chemical functionalization tends to reduce the aspect ratio of the nanotubes and consequently, the percolation threshold will be increased (Haghgoo *et al.*, 2019).

Industrial Applications of Polymer Nanocomposites

Recently, PNCs have found huge commercial potential in many areas, as they have superior properties in comparison with traditional polymers. The tremendous properties of the PNCs and their flexible functionalities make them attractive for different industrial fields of application from energy storage to biomedicine, some of the common ones are illustrated in Fig. 2 (Mansor and Akop, 2020; Klefenz, 2004; Sunday *et al.*, 2012; Hossain and Hoque, 2018; Lau *et al.*, 2018; Vatanpour and Safarpour, 2018; Joshi and Kumar, 2018; Bharathidasan *et al.*, 2020; Zare and Shabani, 2016; Anagri *et al.*, 2019; Ansari *et al.*, 2015).

Biomedical and Tissue Engineering Applications

The desirable properties of biopolymer-based materials are attractive for biotechnology applications such as fighting and preventing diseases, using atomic/nano-scale of the functional materials. In this view, biopolymer-based nanocomposites are of great scientific importance in tissue engineering to repair/remove injured tissue/organ. Numerous researches have been done on the applicability of PNCs in medical fields including nerve tissue repairment (Balint *et al.*, 2014), bone regeneration nanocomposite scaffold (Hajiali *et al.*, 2010; Pina *et al.*, 2015), and artificial skin (Suzuki *et al.*, 2000). In tissue engineering, scaffolds are based on a temporary artificial matrix that provides a three-dimensional support structure for cell seeding, proliferation, and new tissue formation (Kumar *et al.*, 2018).

The other important application of PNCs in biotechnology is the smart packaging of food (Pavlović and Pavlović, 2021). This type of packaging offers significant environmental and economic advantages as they are biocompatible/biodegradable and a great gas barrier (Zafar *et al.*, 2016; Cui *et al.*, 2015). The biodegradable nature helps to recover the lacking assets (i.e., degradability) of conventional petroleum-based plastic packaging materials (Duncan, 2011). The incorporation of metal with a strong anti-microbial activity like Zinc (Lemire *et al.*, 2013), clay, or graphene as nanofillers produces a nanocomposite for food packaging application with a maze structure that greatly reduces the permeation of gases (Burdock, 2007; Müller *et al.*, 2017). On the other hand, the use of platelet-shaped nanofillers in a polymer matrix such as layered silicate nanoclays (e.g., montmorillonite (MMT) and kaolinite) produces a tortuous path as a gas barrier structure for liquids and gases and results in a delay in the oxidation of food and beverages. The barrier performance of PNC packages is illustrated in Fig. 3.

Another application of PNCs is the detection and treatment of cancer in terms of identifying tumor cells and selective irradiation of targeted tumor areas (Liu *et al.*, 2014; Peng *et al.*, 2015; Liao *et al.*, 2017; Feldman, 2019).

Fig. 2 Common industrial applications of polymer nanocomposites.

Fig. 3 Barrier performance of polymer nanocomposite packages. Reproduced from Duncan, T.V., 2011. Applications of nanotechnology in food packaging and food safety: Barrier materials, antimicrobials and sensors. *Journal of Colloid and Interface Science* 363, 1–24.

PNCs also have the potential of being a carrier for the controlled release of drug delivery. Liu *et al.* demonstrated the drug delivery of polymer-clay nanocomposites which were prepared by reactive melt extrusion. They proved that the addition of nanoclays into the polymer matrix enhances the drug delivery efficiency of the PNC (Liu *et al.*, 2020).

Energy-Related Applications

In recent years, the increase in the global population has increased the energy demands to provide the required services. Hence, there is a need for the development of efficient, clean, and sustainable energy sources rather than fossil fuels. Renewable energy sources are a suitable alternative to fossil fuels due to the tight environmental regulations and depletion of natural fossil fuels (Sarwar *et al.*, 2017). Polymeric nanocomposites also find applications in generating green and environment-friendly energy. Some techniques have been developed based on the PNCs for the conservation and storage of electrochemical energy such as fuel cells (Kim *et al.*, 2015), solar cells (Lasrado *et al.*, 2020), lithium-ion batteries (LIBs) (Masoud *et al.*, 2020), and supercapacitors (Sahoo, 2017).

Fuel cells are the devices that convert stored chemical energy into fuels like hydrogen, methanol, ethanol, and formic acid (Hossain and Hoque, 2018). They are known to have the merit to be great alternatives to fossil fuels since they are highly efficient and do not produce any pollution such as SO_x , NO_x , and CO_2 in comparison with coal combustion engines. Fuel cells are classified into five different types based on the mode of operation, operation temperature, and nature of electrolyte. Among them, polymer electrolyte membrane (PEM) is the most promising for the generation of power for portable devices, automotive, and stationary applications (Mehta and Cooper, 2003). Different types of PNCs have been explored to be used to enhance the performance of conventional proton conducting membranes such as Nafion, sulfonated poly (ether ether ketone) (SPEEK), poly (ether sulfone) (PES), and poly(benzimidazole) (PBI) (Chen *et al.*, 2012). They possess superior properties such as high proton conductivity and excellent thermal and mechanical stability at low humidity and high temperature (Luo *et al.*, 2016).

CNT and graphene and its derivatives, as nanofillers, can also be used to boost performance and reduce the cost of polymer solar cells (PSCs) by enhancing their different constituents, such as glass electrodes, liquid electrolytes, and catalyst layer (Saleh *et al.*, 2020). Another outstanding photovoltaic technology is dye-sensitized solar cells (DSSCs), which is a low-cost and high-efficiency method for the generation of energy. The only drawbacks of this method are the presence of expensive and brittle fluorine-doped tin oxide glass coated with a platinum film cathode and stability issues due to leakage and volatilization of organic solvents. Rehman *et al.* recently synthesized a polyvinyl acetate (PVAc)/graphene nanocomposite-based gel electrolyte for the first time using the in-situ intercalative polymerization technique to enhance the efficiency of the solar cells. Their results showed an increase in the photovoltaic conversion efficiencies (PCEs) from 4.35% to 4.57% (Rehman *et al.*, 2020). In another study, Bayram *et al.* produced graphene/polyaniline nanocomposite thin films as counter electrode materials to be used in place of platinum (Pt)-counter electrode. Their results confirmed the successful replacement of PNCs with the platinum electrode in dye-sensitized solar cells (Bayram *et al.*, 2020).

Another popular application of PNCs is in LIBs. Having high voltage, huge power, low toxicity, and long life cycle has made the LIBs more popular for their application as a rechargeable battery in recent years (Ding *et al.*, 2014). Intrinsically conductive polymers (ICPs) have attracted significant research efforts to improve the performances of conventional LIB electrode materials. The electroactive organic functional groups in the ICPs have faster redox reaction kinetics than conventional inorganic LIB electrode materials (Yang *et al.*, 2015). Arya and Sharma prepared a PNC based on blend PEO-PVC, LiPF_6 as salt, and modified montmorillonite (MMMT) as nanoclay by solution cast method for application in LIBs. According to their results, an increase in the fraction of free anions, thermal stability (up to 300 °C), ion transference number (~ 1), and voltage stability window of ~ 5 V was observed with the addition of clay into the polymer matrix for a LIB (Arya and Sharma, 2020).

In another application, PNCs can be used in supercapacitors. Among different techniques for energy storage such as fuel cells, solar cells, LIBs, and supercapacitors, the supercapacitors possess the advantage of high-power density due to the fast-electrical energy storage and discharge capability. The higher specific capacitance value of the conducting polymer nanostructures makes them an alternate in the development of the next-generation energy storage devices (Mishra and Valodkar, 2017; Wang and Zhu, 2011). Khan *et al.* prepared an electrode material based on composites of polyaniline, graphite nanoplatelets (GNP), and polystyrene matrix (PANI/GnP/PS). Their results showed that PANI/GnP/PS nanocomposite exhibited a lower reduction (32%) in the specific capacitance after 1600 charge-discharge cycles compared to other electrodes, demonstrating it as an ideal electrode in supercapacitors (Khan *et al.*, 2020).

PNCs also receive a widespread attraction for application in high-voltage cable insulations. Paramane *et al.* prepared a cross-linked polyethylene (XLPE)/MgO nanocomposite material and investigated its performance for the insulation of commercial 320 kV high-voltage direct-current (HVDC). Based on their observations, the direct-current (DC) breakdown strength of the prepared nanocomposite was improved by 20% due to the higher deep trap density and lower charge carrier mobility. They also studied the effect of thermal aging on the insulation performance of the PNC. The thermally aged nanocomposite showed greater restraint against the degradation of its properties. The DC breakdown strength also decreased after thermal aging by 38% and 20% in the pure XLPE and its nanocomposite, respectively (Paramane *et al.*, 2020). The successful application of PNCs for high voltage insulation has been also confirmed by other researchers (Li *et al.*, 2020; Yu *et al.*, 2020; Lau and M. Piah, 2011).

Corrosion Protection Applications

Corrosion which usually involves the oxidation of the metal and the reduction of oxygen, protons, and/or water, is a global challenge with a cost of \$2.5 trillion annually worldwide (Umoren and Solomon, 2019). Corrosion protection has become an issue of great concern in the modern metallic finishing industry (Yang *et al.*, 2015). Different strategies have been employed to combat corrosion, among which the use of corrosion inhibitors and coatings are the most popular ones. However, common organic inhibitors cannot provide long-term corrosion protection because of their brittle structure and hydrolytic degradation during exposure to a corrosive environment. Research has shown that the introduction of inorganic nanoscale materials into the polymer matrices could remarkably increase the corrosion inhibition efficiency (Umoren and Madhankumar, 2016; Salehoun *et al.*, 2017; Solomon *et al.*, 2017). Different types of nano-sized fillers have been used in different researches to improve the barrier protection of polymer coatings and reduce the permeability of aggressive species into the coatings, such as inorganic nanomaterials (Atta *et al.*, 2019), layered doubled hydroxides (Olya *et al.*, 2020), clays (Davoodi *et al.*, 2020), and graphene-based nanomaterial (Javidparvar *et al.*, 2020). Pourhashem *et al.* demonstrated that incorporation of inorganic nanomaterials including metal and metal oxides, nano-glass flakes, nitrides, and borides, and nano-calcium carbonate into a polymer matrix produces

Fig. 4 Corrosion protection mechanism of polymer coatings containing inorganic nanomaterials: (a) barrier performance; (b) increasing water contact angle; (c) increasing adhesion strength at coating/metal interface; (d) sacrificial protection; and (e) passive layer formation. Reproduced from Pourhashem, S. Saba, F., Duan, J., *et al.*, 2020. Polymer/inorganic nanocomposite coatings with superior corrosion protection performance: A review. *Journal of Industrial and Engineering Chemistry* 88, 29–57.

corrosion-resistant coatings. On the other hand, the other aspects of coatings including thermal stability, UV resistance, weathering resistance, mechanical performance, and hydrophobic property can be improved along with the corrosion resistance (Fig. 4) (Pourhashem *et al.*, 2020).

Ballistic, Aerospace, and Automobile Applications

Another application of PNCs is in the automobile and aerospace industry. The size scale, aspect ratio, and properties of nanofillers such as nanotubes provide great advantages for PNCs to be used for different applications such as electrostatically dissipative materials, advanced materials with combined stiffness and strength for application in aerospace or sporting goods, composite mirrors, and automotive parts that require electrostatic painting and automotive components with enhanced mechanical properties (Sahoo and Tripathy, 2017). Moreover, a 10% reduction in automobile weight can improve fuel efficiency by 6–8%, so this industry needs to develop lightweight materials. Toyota Motor Company was the first who pioneered the first practical example of polymeric nanocomposite for automobile applications (Garces *et al.*, 2000). Besides, Japan developed a reinforced elastomer comprising elastomer-based materials (including natural rubber, butadiene rubber copolymers, and polychloroprene rubbers) and a modified clay PNC, using as the engine cover in Mitsubishi vehicles (Carter *et al.*, 1947). Ford Motor Company has indicated that weight reduction is a key part of its strategy to improve fuel economy by 40% by the year 2020. They have planned the company's goal to reduce vehicle weight as much as 750 lbs (340 kg), depending on the model, without compromising safety. To achieve the goal, one path that Ford scientists are taking is the replacement of metal with PNCs (Stewart, 2009).

The mechanical properties of the PNCs can be drastically enhanced, by a little increment in the material cost. This enables them to be cost-competitive in comparison with traditional polymers and finally, replace the metal and glass in the vehicle. As a result, the automotive industry is enabled to capture a leadership position in high-quality, fuel-efficient, fast production, and durable vehicles (Garces *et al.*, 2000).

Fig. 5 General application of composites with respect to other materials in commercial airplanes. Reproduced from Behera, A., Mallick, P., 2020. Chapter 20 – Application of nanofibers in aerospace industry. In: Han, B., Sharma, S., Nguyen, T.A., Longbiao, L., Subrahmanya Bhat, K. (Eds.), *Fiber-Reinforced Nanocomposites: Fundamentals and Applications*, Elsevier. pp. 449–457.

Fig. 6 The general processes of an incident EM wave through an EM absorption material. Reproduced from Rani, P., Ahamed, M.B., Deshmukh, K., 2020. Significantly enhanced electromagnetic interference shielding effectiveness of montmorillonite nanoclay and copper oxide nanoparticles based polyvinylchloride nanocomposites. *Polymer Testing* 91, 106744.

For aircraft flying at high altitudes, some properties such as low solar absorption, radiation resistance, high thermal emissivity, resistance to corrosion, and electrical conductivity are important (Rathod *et al.*, 2017). The addition of different concentrations of nanofillers such as fibers, whiskers, platelets, and CNTs to the composites, the previous properties could be usually fulfilled. Depending upon the matrix and nanofiller, PNCs can be used in the airplane turbine engine (for protection of turbine blades against high-speed particle impact) (Lee *et al.*, 2012), fuselage (for weight and cost reduction and corrosion protection), horizontal and vertical stabilizers, and nose (Behera and Mallick, 2020). Fig. 5 illustrates different types of materials including composites used in the structure of commercial airplanes with a comparison between their compositional percentage.

Electromagnetic interference (EMI) shielding is another important application of PNC. EMI shields can be used to protect humans or devices from being harmed or something such as airplanes from being detected. PNCs are ideal EM wave absorbers due to their relatively lightweight, thin thickness, high EM absorption, tunable absorption characteristics, broad width, etc. (Abbasi *et al.*, 2019). Fig. 6 displays the general process of an incident EM wave through an EM absorption material.

Among different types of polymer matrices, Ling *et al.* reported a facile approach to produce lightweight microcellular polyetherimide (PEI)/graphene nanocomposite foams with a density of about 0.3 g/cm^3 by a phase separation process. They demonstrated that PEI/graphene nanocomposite foams exhibited well-defined thermal insulation and tensile properties. Furthermore, they reported that the specific EMI shielding effectiveness of microcellular PEI/graphene foams was $36.1 \text{ dB/(g/cm}^3\text{)}$ and

44.1 dB/(g/cm³) for 7 wt% and 10 wt% loading, respectively, which was about 2.2 and 2.5 times higher than the unfoamed counterparts (Ling *et al.*, 2013).

Singh and Kulkarni presented the application of the nanocomposites based on different transition metal oxides like iron oxide (Fe₂O₃), zinc oxide (ZnO), silicon dioxide (SiO₂), zirconium dioxide (ZrO₂), and titanium dioxide (TiO₂) in the Polyvinyl alcohol (PVA) matrix for their suitability as EMI shielding materials in the frequency range of 4–8 GHz (C-band) and 8–12 GHz (X-band). They prepared different concentrations of nano-oxides from 0.1, 0.5, 1.0, 5.0, and 10.0 wt% in a PVA matrix and synthesized the PNCs via the solvent casting method. Based on their experimental results, the reflectivity decreases by increasing the nano-oxides concentration and the minimum reflectivity values of PVA–SiO₂, PVA–Fe₂O₃, PVA–ZnO, PVA–TiO₂, and PVA–ZrO₂ at 10 wt% concentration of nano-oxides were –41.9 dB (10.4 GHz), –38.85 dB (10.4 GHz), –33.65 dB (10.4 GHz), –32.90 dB (9.76 GHz), and –24.90 dB (11.0 GHz), respectively. All of the composites exhibit very good thermal stability and high mechanical strength, making them more promising for EMI shielding applications (Singh and Kulkarni, 2014).

Ultraviolet Protection Applications

UV light is known to be harmful to all living beings. Many different methods have been developed to protect against UV radiations such as sunglasses, sunscreen lotions/creams, window protectors, and clothes. Another cost-effective method to provide protection against UV-rays is UV-shielding PNCs. However, most traditional UV protectors provide good UV-block performance, they suffer from photodegradation, migration, and aggregation. Several researchers have confirmed the high UV-shielding performance of different bio-inspired PNCs such as dopamine-melanin solid nanoparticles (Dpa-s NPs) and hollow nanoparticles (Dpa-h NPs) (Wang *et al.*, 2017), polyacrylonitrile (PAN)/multi-walled carbon nanotubes (MWCNTs) composite (Nasouri, *et al.*, 2020), and composite-based polyethylene terephthalate (PET) (Bouazizi *et al.*, 2020).

Sensors Applications

In recent years, polymer-nanocomposites have been used for sensing applications such as gas sensors, biosensors, and chemical sensors. Different types of nanofillers can be employed for this purpose including metal oxide nanowires, CNTs, nanoscale gold, silver, nickel, copper, platinum, and palladium particles (Saleh *et al.*, 2020). The resulting PNC sensors are designed to be sensitive to the pH changes, possess an affinity for organic molecules and inorganic ions, and monitor the existing pathogens. In some researches, their applicability was successfully determined in the detection of free chlorine, ferricyanide, ammonia and amines, bisphenol A, ibuprofen, and (chemical oxygen demand/dissolved oxygen) COD/DO levels in aqueous systems (Cheng *et al.*, 2016; Muñoz *et al.*, 2015; Motoc *et al.*, 2013; Akharam *et al.*, 2018).

Smart Polymer Nanocomposites Applications

Recent advances in PNCs have led to the development of smart PNCs with scientific and industrial potential in various application areas such as shape memory, self-healing, self-sensing, self-cleaning, and energy harvesting (Idumah, 2019). Smart PNCs are used for different purposes such as sensors/actuators (Kumar *et al.*, 2020), wearable electronics, smart textiles (Elhalawany *et al.*, 2020), drug delivery (Zhang, *et al.*, 2013), stretchable electronics, and aerospace applications (Zhu *et al.*, 2019).

A smart textile was fabricated based on the conjugated polymers by Lee *et al.*, by assembling a conjugated polymer with a fatty acid via an emulsion process and distributing the fiber nanoparticles in a polyacrylonitrile matrix. Based on their results, the textiles showed an excellent photothermal temperature from 25°C to 55°C in 10 min, because of efficient photothermal conversion under white light irradiation. Besides, the smart PNC textile showed better antimicrobial activity and strong colorfastness than Ag nanofillers, demonstrating their practical application in the textile industry (Lee *et al.*, 2019).

Wan and Chen synthesized a smart PNC coating from waterborne polyurethane and graphene oxide (GO). They prepared a series of self-healing waterborne polyurethane/GO nanocomposites with different concentrations using the solution blending method. Their results showed a 22%–47% enhancement in the tensile strengths of the nanocomposites compared with that of neat waterborne polyurethane. On the other hand, the sample containing 0.5 wt% GO showed the best self-healing performance, as obvious in Fig. 7 (Wan and Chen, 2018).

Adhesive Applications

The first reports regarding the synthesis of the first adhesives date back to 1920. Since then many efforts have been done to develop synthetic polymers as adhesives. In recent years, many studies have shown that the incorporation of nanoparticles into polymeric adhesives enhances their performance (Cudjoe *et al.*, 2018). Luo *et al.* studied the effect of the addition of nanoparticles into thermoplastic polyurethane adhesives (TPU). They found that the use of silver flakes and CNTs as nanofiller enhanced the mechanical, electrical, and thermal properties of the nanocomposites. Moreover, the electrical conductivity was increased by 86.6% after the addition of 4.5 wt% CNT into the 50 wt% Ag TPU adhesives (Luo *et al.*, 2016).

Khalina *et al.* studied the preparation of a pressure-sensitive adhesive, comprising of a definite ratio of 2-ethylhexyl acrylate/acrylic acid/methyl methacrylate (2-EHA/AA/MMA) monomers and nanosilica fillers. They found that the addition of 0%–4%

Fig. 7 (a) Microscope images of cracked SHWPU/GO films at different healing time and (b) Surfaces topography images of cracked SHWPU/GO films before and after healing at 70 °C for 10 min. Reproduced from Wan, T., Chen, D., 2018. Mechanical enhancement of self-healing waterborne polyurethane by graphene oxide. *Progress in Organic Coatings* 121, 73–79.

nanosilica increases viscosity, elastic modulus, and loss modulus. Based on the analysis of adhesion properties such as tack, peel, and shear strength for the nanocomposite films containing 4 wt% of nanosilica, a significant improvement of up to 300% was observed in the tack resistance. (Khalina *et al.*, 2015).

Flame Retardant Polymer Nanocomposites

Despite the outstanding properties of PNCs such as lightweight, superior mechanical properties, high chemical stability, corrosion resistance, easy processing procedure, and high specific strength, they suffer from intrinsic flammability, arises from their chemical structures and organic compositions. Fig. 8 represents a schematic for a typical combustion process of polymers. This property significantly restricted the practical applications of PNCs in electronics, building, automotive, transport, textile, and aerospace fields. To overcome this limitation, many researchers have addressed the synthesis of flame retardant PNCs (He *et al.*, 2020; Wang *et al.*, 2011; Kong *et al.*, 2017; Xu *et al.*, 2020; Higginbotham *et al.*, 2009; Morgan and Wilkie, 2007). The presence of nanoparticles can reduce the flammability of PNCs by decreasing the heat release rate and increasing the ability to flame-out and auto-extinguish (Morgan and Wilkie, 2007). Higginbotham *et al.* developed a GO PNC at 1, 5, and 10 wt% GO with polycarbonate (PC), acrylonitrile butadiene styrene (ABS), and high-impact polystyrene (HIPS), to study the influence of nanoparticle addition on the flammability reduction of PNCs. They observed an increase in the storage modulus by increasing the GO loading. Besides, the addition of GO reduced the total/peak heat release rates in all systems, and GO-PC composites demonstrated very fast self-extinguishing times in vertical open flame tests, which are important to some regulatory fire safety applications (Higginbotham *et al.*, 2009). Their work revealed that GO nanoparticles are promising additives for the fabrication of flame-retardant PNCs.

Kong *et al.* studied the improvement in flame retardant properties of intumescent flame retardant/polypropylene (IFR/PP) through the synergistic effect of organic montmorillonite intercalation cobalt hydroxides (Co-OMMT) modified by acidified chitosan. They fabricated the Co-OMMT/IFR/PP nanocomposites via the melt blending method. The results of limiting oxygen index (LOI) and vertical burning (UL-94) tests indicated that IFR/PP composites only reached a V-2 rating with the LOI value of 26.5%. An addition of 4 wt% of Co-OMMT nanoparticles into the IFR/PP matrix resulted in a flame-retardant nanocomposite that passed UL-94V-0 rating with a higher LOI value of 32.1%. Furthermore, based on the results of CC tests, the values of peak heat release rate (PHRR), total heat release (THR), and peak smoke production rate (PSPR) of 4 wt% Co-OMMT/IFR/PP nanocomposites decreased by 33.7%, 11.8%, and 16.7%, respectively, compared to that of IFR/PP. This may be due to the formation of

Fig. 8 Schematic representation for a typical combustion process of polymers. Reproduced from He, W., Song, P., Yu, B., Fang, Z., Wang, H., 2020. Flame retardant polymeric nanocomposites through the combination of nanomaterials and conventional flame retardants. *Progress in Materials Science* 114, 100687.

the compact char protection layers in the condensed phase during burning, which efficiently inhibited the heat and mass transmission and prevented organic degradation volatiles from getting into the gas phase (Kong *et al.*, 2017).

Wang and co-workers reported the flame-retardant systems consisting of nano-ZrO₂ and triphenyl phosphate (TPP) for PMMA. The results of the CC test, TGA, Raman spectra, SEM, and X-ray photoelectron spectroscopy (XPS) confirmed the synergistic effect of nano-ZrO₂ with TPP for PMMA polymer matrix. A reduction in the peak heat release rate and an increment in the thermal stability was observed by increasing the content of nano-ZrO₂, confirming the flame retardancy of the obtained PNC material (Wang *et al.*, 2011).

Conclusion

Nowadays, with the increase in industrialization, polymers have found application in many fields of engineering from automobiles through biomedical applications, energy-related applications, coatings and corrosion protection, ballistic and aerospace applications, UV protection, sensors, and adhesive applications. Lack of some features such as flammability, conductivity, biocompatibility, and good mechanical properties has limited their application for certain practical purposes. Adding nanoparticles into the polymer structure leads to the formation of PNCs, which to some extent resolves the issues with single polymers. In this article, different types of nanocomposites and their properties, advantages, and disadvantages are first described with a high focus on the PNCs. Then a detailed explanation is given to describe their characterization techniques including structural analysis, thermal properties, mechanical properties, and electrical properties. Finally, the various industrial applications of the PNCs such as biomedical and tissue engineering applications, energy-related applications, corrosion protection applications, ballistic, aerospace, and automobile applications, UV protection applications, sensors applications, smart PNCs applications, adhesive applications, and flame-retardant PNCs are described in detail.

Introduction

A composite material is a combination of two or more distinct materials into one with the intent of suppressing the undesirable properties of the constituent materials in favor of the desirable properties [1]. Fiber-reinforced plastic (FRP) composites are typically fabricated using a polymer matrix, such as epoxy, vinyl ester, or polyester and reinforced with various grades of carbon, glass, and/or fibers [1].

Polymers are playing an important role in the contemporary world for a number of applications ranging from daily needs to the biomedical and defense fields [2]. Recently the field of polymer science has attracted greater attraction from the research community due to the enormous advantages offered by polymer based materials, and several polymers are appearing from the laboratories of scientists with unique and important properties for advanced applications [2]. Polymer based composite materials have been playing an important role in niche applications in the last few decades, ever since the discovery of Bakelite resin [2]. These materials are emerging rapidly as a potential substitute for metal or ceramic based materials in a number of fields including automotive, aerospace, marine, sporting goods, and electronic industries, etc. [2]. Among the various composite materials, natural FRP composites are coming under increasing scrutiny due to their easy processing and enormous eco-friendly advantages [2]. The potential advantages present in the use of FRP composites include: higher strength, lighter weight, higher performance, longer lasting, rehabilitating existing structures and extending their life, seismic upgrades, defense systems' unique requirements, space systems, and ocean environments [1].

Two commonly used glass fibers in the industry are E-glass and S-glass. The primary material in most glass fibers is silica; to effectively produce these fibers, the ingredients must be melted in a furnace at a temperature of about 1370 °C. Glass fibers are a popular choice for fiber reinforcement due to their advantageous properties such as high strength (tensile strength of approximately 3.40 GPa), tolerance to high temperatures and corrosive environments, and low cost [1].

FRP composites are extremely important in industry and have attracted tremendous attention [3]. Glass fiber (GF) has stimulated tremendous interest as a reinforcement for the polymer matrix due to its very low cost, high mechanical property, good heat and resistance [3]. For GF/polymer composites, the interface between the GF and the polymer plays an important role in controlling some of the mechanical properties. In order to obtain high-performance FRP composites, high interfacial strength is the key issue [3]. FRP composites are widely used in many engineering applications involving wide temperature changes such as in aircraft structural components and wind turbine blades, and for retrofitting nuclear reactor containment concrete structures, etc. [4, 5]. In previous research, a fiber angle of 45 degrees and 8 layers of glass fiber were investigated [6]. Among all the geometries, the 45 degree geometry was found to have the highest Filtration Index. The 45 degree geometry indicated a Filtration Index improvement of up to 4.3 times that of the base case.

The objectives of this research are to study the mechanical properties through tensile testing of woven fabric glass epoxy composite laminates. The orientations of the glass composites are 90, 60, and 45°.

Theory

Definition of Composites

A composite material is made by combining two or more materials to give a unique combination of properties. It can include metal alloys, plastic co-polymers, minerals, and wood. Fiber-reinforced composite materials differ from these materials in that the constituent materials are different at the molecular level and are mechanically separable. In bulk form, the constituent materials work together but remain in their original forms. The final properties of composite materials are better than the constituent material properties [7].

The concept of composite materials was not invented by human beings; it is found in nature. An example is wood, which is a composite of cellulose fibers in a matrix of natural glue called lignin. Scientists have found that the fibers taken from a spider's web are stronger than synthetic fibers. The main concept of a composite is that it contains matrix materials. Typically, composite material is formed by reinforcing fibers in a matrix resin as shown in Fig. 1. The reinforcements can be fillers in particulates, or whiskers, and the matrix materials can be metals, plastics, or ceramics. The fibers can be continuous, long, or short. Composites made with a polymer matrix have become more common and are widely used in various industries. The reinforcing fiber or fabric

Fig. 1 Formation of a composite material using fibers and resin [7].

Fig. 2 Continuous fiber and short fiber composite [7].

provides strength and stiffness to the composite, whereas the matrix gives rigidity and environmental resistance. Reinforcing fibers are found in different forms, from long continuous fibers to woven fabric to short chopped fibers and mat. The properties strongly depend on the way the fibers are laid in the composite. The important thing about composites is that the fiber carries the load and its strength is greatest along the axis of the fiber. Long continuous fibers in the direction of load result in a composite with properties far exceeding the matrix resin itself. The same material chopped into short lengths yields lower properties than continuous fibers, as illustrated in Fig. 2.

Phases of Composites

A composite material is formed by reinforcing plastics with fibers. The important functions of fibers and matrix materials are discussed in the following sections [7].

The main functions of the fibers in a composite are:

1. To carry the load. In a structural composite, 70–90% of the load is carried by the fibers.
2. To provide stiffness, strength, thermal stability, and other structural properties in the composites.
3. To provide electrical conductivity or insulation, depending on the type of fiber used.

A matrix material fulfills several functions in a composite structure, most of which are vital to the satisfactory performance of the structure. Fibers by themselves are of little use without the presence of a matrix material or binder.

The important functions of a matrix material include the following:

1. The matrix material binds the fiber together and transfers the load to the fibers. It provides rigidity and shape to the structure.
2. The matrix isolates the fibers so that individual fibers can act separately. This stops or slows the propagation of a crack.
3. The matrix provides a good surface finish quality and aids in the production of net-shape parts.
4. The matrix provides protection to reinforcing fibers against chemical attack and mechanical damage (wear).
5. Depending on the matrix material selected, performance characteristics such as ductility, impact strength, etc. are also influenced. A ductile matrix will increase the toughness of the structure. For higher toughness requirements, thermoplastic-based composites are selected.
6. The failure mode is strongly affected by the type of matrix material used in the composite as well as its compatibility with the fiber.

Table 1 Glass grades for fiberglass [8]

Type	Description
A	Glass of soda-lime composition similar to bottle glass. Poor thermal and chemical properties, not used for fibers.
C	Chemically resistant soda-lime-borosilicate glass used for its high corrosion and chemical attack resistance.
D	A low-density glass with high electrical resistance.
E	Pyrex composition glass. Good electrical properties and good for general-purpose application when a combination of good strength and chemical resistance is observed.
S	A high-strength, high-modulus glass for specific applications. Higher in cost.

2.2.1 Fiber

Fiber for composite materials can come in many forms: discontinuous fibers, long fibers, short fibers, organic fibers, inorganic fibers. The most widely used materials in FRPs are glass, carbon, aramid, and boron [7].

2.2.1.1 Fiberglass

Fiberglass is one of the most versatile and most widely used fibrous reinforcing materials. Due to its extensive usage, it is available in a wide variety of configurations, including continuous filaments with twisted or parallel strands, short chopped fibers, woven cloth, rovings, and preregs. Glass fibers are produced by passing molten glass through a platinum crucible (the bushing) which contains many small holes (tips) through which the glass is drawn, forming the fibrous material. Immediately on passing through the tips, the drawn glass fibers are subjected to a carefully controlled water spray and a humidity- and temperature-controlled air blast for rapid cooling. The glass is then coated with an appropriate size and then wound on mandrils for packaging and further handling. The sizing is usually a starch-oil emulsion which absorbs water to provide lubrication during the subsequent winding and handling operations.

Fibers are manufactured in the range of 10–25 μm . The thinner-diameter fibers can be more easily wetted and coated by resin and provide a better drape to contour accurately a complex mold. However, they are more difficult to produce and require more care in handling. **Table 1** lists the various glass grades available in fibers. Glass fibers are amorphous and behave elastically until their breaking point, failing with about 3% elastic strain. Over 90% of the fiberglass used for reinforcement is of the E-glass type. This glass has excellent electrical properties and good mechanical properties and bonds well to most plastics after an appropriate coupling agent is employed. S-glass is higher in strength but difficult to manufacture and is utilized primarily in aerospace applications where strength is critical. Chemically resistant C-glass is utilized when chemical resistance is a critical requirement. The C-glass is usually employed as an outer layer with the more customary E-glass as the bulk of the fiberglass structure [8].

Carbon fiber

Carbon and graphite fibers are produced using polyacrylonitrile (PAN) and pitch. Fibers of these starting materials are produced by the techniques for fiber manufacture, in which a solution of the polymer is forced through a spinneret head containing minute holes to produce fine fibers. These starting fibers are converted to carbon by decomposition at elevated temperature in a series of heating steps in air and inert atmospheres to temperatures as high as 3000 $^{\circ}\text{C}$. All components except the carbon evaporate at these temperatures, and the crystal structure changes simultaneously. The fibers are stretched to align the molecules along the fiber axis, either prior to or concurrent with the heating process. The graphite fibers are given various surface treatments, and coupling agents are applied to the surface to improve their compatibility with the resin matrix [8].

Aramid fiber

Aramid fiber (trade name Kevlar) is manufactured by Dupont [8]. Aramid fibers provide the highest tensile strength-to-weight ratio among reinforcing fibers. They provide good impact strength like carbon fibers; they provide a negative coefficient of thermal expansion. The disadvantage of aramid fibers is that they are difficult to cut and machine [7].

Boron fiber

The modulus of boron is the highest of the high-strength fibers, and boron is used in applications where maximum stiffness is required. The boron fibers are manufactured starting with boron trichloride (BCl_3), which is reduced with hydrogen to generate the boron. Due to its high cost and the difficulties associated with handling boron, this material is less commonly used than carbon or Kevlar fiber.

Matrix material

Matrix materials are compounded with reinforcing materials. Among the fibers, glass is the main reinforcement. Examples of these matrix materials are as follows:

Epoxy

The starting materials for the epoxy matrix are low molecular weight organic liquid resins containing a number of epoxide groups, which are simply three-membered rings with one oxygen and two carbon atoms (**Fig. 3**).

Fig. 3 Characteristic group for epoxies [9].

Fig. 4 Difunctional epoxy (1), epoxidised novolak (2), and tetraglycidyl methylene dianiline (3) [9].

Fig. 5 New generation aromatic and glycidyl amine resins [9].

Epoxides can vary from difunctional to polyfunctional. After their reaction with the curing agents (which occurs without the evolution of any by-product), they yield to high performance systems with a combination of high rigidity, solvent resistance and elevated temperature behavior. The most widely used difunctional epoxy is the diglycidyl ether of bisphenol A, with (n) from 0.2 to 12 (formula 1 in Fig. 4) with the use of different types of curing agents, i.e., various amines. Epoxidised novolaks (formula 2) possess multi-epoxy functionality of at least 2, or more than 5, epoxy groups per molecule.

For high temperature aerospace applications, a special polyfunctional epoxy with aromatic and heterocyclic glycidyl amine groups, i.e., tetraglycidyl methylene dianiline (TGMDA; formula 3), is used.

A new generation of aromatic and glycidyl amine resins with improved hot/wet temperature characteristics is also available (formulae 4 and 5 in Fig. 5). There are, in addition, a number of special multi-functional epoxides formulated with TGMDA and/or bisphenol A.

Curing agents used for epoxides are either co-reactants (become incorporated with the epoxide during the reaction), or act as a catalyst to promote crosslinking. The first type of curing agent is polyfunctional and can be basic (primary/secondary amines, polyaminoamides) or acidic (anhydrides, polyphenols, polymeric thiols). Depending on the basicity or acidity of the curing agent,

curing may occur at room or at high temperatures. Catalytic curing agents (tertiary amines and BF_3 complexes) can accelerate curing at low or at ambient temperatures.

Selection of the epoxy resin for any composite application is usually done by considering the final application conditions of the composite, since there are significant differences existing between the thermal and mechanical properties of different epoxides, i.e., in moduli, in strain to failure and in T_g , and usually there is a compromise between the high temperatures and toughnesses. That is, the T_g controls the application temperature, which is high (247°C) for brittle epoxides, but much lower for toughened epoxides. The degree of polymerization can also affect processability and crosslink densities. In addition, the type of curing agent or accelerator and its molar ratio to the epoxy affects some of the final properties of the epoxy system, and these must be optimized, because of a change in crosslink densities. For structural applications, the hardener dicyandiamide (DICY) is usually used. By careful selection of the polymer and curing agent to accelerator ratio, and their use with the optimized values, the properties of the final product can be assured. In addition, there are a number of methods and strategies which have been developed for the combination of the most desirable features of a thermoplastic resin segment within the epoxy resin to form a multi-component composite system. A considerable amount of research has been done to further improve the toughness, moisture resistance and heat stability of epoxy matrices. These studies led to the production of epoxy composite systems for subsonic aircraft with the desired tensile-compressive moduli and tensile strength values of 138 GPa and 1930 MPa. In comparison, a tensile-compression modulus of 3100 MPa and a tensile strength value of 96 MPa was recorded for the neat resin.

Epoxy resins have the added advantage over many other thermosets in that, since no volatiles and condensation products other than the polymer product are produced during cure, molding does not require, in principle, high pressure molding equipment. By use of the epoxy matrix, one can gain a system with the following advantages [9]:

- 1) a wide variety of properties,
- 2) low shrinkage during cure (lowest within thermosets),
- 3) good resistance to most chemicals,
- 4) good adhesion to most fiber, fillers,
- 5) good resistance to creep and fatigue, and
- 6) good electrical properties.

Conversely, the following principal disadvantages may apply:

- 1) Sensitivity to moisture (after moisture absorption (1–6%), there is usually a decrease in the following: heat distortion point, dimensions and physical properties),
- 2) difficulty in combining toughness and high-temperature resistances (as explained above),
- 3) high CTE as compared to other thermosets,
- 4) susceptibility to UV degradation, and
- 5) cost (epoxies are more expensive than polyesters).

Phenolics

Phenolics (produced by reacting phenol with formaldehyde/PE) were the original major commercially viable synthetic thermoset (TS) plastic materials. They have low creep, excellent dimensional stability, good water and chemical resistance, heat resistance and good weatherability. Phenolic resins are inherently brittle, giving poor impact performance, but by adding materials such as siloxane and glass fibers this is significantly increased.

Compounds from these resins have been produced with glass, natural, and other fibers. Principally compression, transfer, and injection molding are used to process them. There are phenolics that when processed release water and others that do not release water. They offer an advantage compared with TS polyesters: i.e., a degree of good inherent resistance to heat and combination. Compared to most other materials they have lower mechanical properties [10].

Polyesters (TS)

Polyesters are low-cost resin systems and offer excellent corrosion resistance. Polyester can be a thermosetting resin and a thermoplastic resin [8]. Polyesters can be used on their own in applications such as casting and encapsulation/potting and in pastes and concretes. Their largest field of application, however, is in reinforced polymers (RPs), where glass fiber in different forms is the main type of reinforcement, offering a cost/performance profile that complements that of the resin. There are many variations of resin on the market, adapted to different applications [10].

Fabrics

There are two major types of fabrics available in the composites industry: woven fabrics and nonwoven (noncrimp) fabrics [7].

Woven fabrics

Woven fabrics are used in trailers, containers, barge covers and water tower blades, and in other marine wet lay-up applications. These fabrics are woven yarns, rovings, or tows in mat in a single layer. Common weave styles are shown in Fig. 6. The amount of fiber in different directions is controlled by the weave pattern. For example, in unidirectional woven fabrics, fibers are woven in

Fig. 6 Various weave styles for fabrics [7].

Fig. 7 Schematic of noncrimp fabrics [7].

such a way that the fibers in 0° are up to 95% of the total weight of the fabric. In a plain-weave pattern, fibers in 0° and 90° directions are equally distributed.

Noncrimp fabrics

In noncrimp fabrics, yarns are placed parallel to each other as shown in Fig. 7 and then stitched together using polyester thread. Warp unidirectional fabric is used when fibers are needed in one direction only. In fabrics, reinforcements are laid 0° (or warp direction) only as shown in Fig. 8; whereas in weft unidirectional fabrics, reinforcements are laid at 90° (or weft direction) only as shown in Fig. 9. Weft fabrics are typically used in filament wound tubes and pipes and also pultruded components where reinforcement in the weft direction is necessary [7].

Mechanical Properties

Stress-strain diagram

In order to relate the loads on engineering structures to the deformation produced by the loads, experiments must be performed to determine the load-deformation behavior of the materials used in fabricating the structures. Many useful mechanical properties are obtained from tension tests or compression tests [11]. A basic understanding of the stress-strain behavior of materials is of utmost importance to design engineers. One such typical stress-strain (load-deformation) diagram is illustrated in Fig. 10 [12].

Stress: the force applied to produce deformation in a unit area of a test specimen. Stress is a ratio of applied load to the original cross-sectional area.

Strain: the ratio of the elongation to the gage length of the test specimens, or simply stated, the change in length per unit of the original length ($\Delta l/l$). It is expressed as a dimensionless ratio.

Elongation: the increase in length of the test specimen produced by a tensile load.

Yield point: the first on the stress-strain curve at which an increase in strain occurs without an increase in stress.

Fig. 8 Warp unidirectional fabrics [7].

Fig. 9 Weft unidirectional fabrics [7].

Yield strength: the stress at which a material exhibits a specified limiting deviation from the proportionality of stress to strain. Unless otherwise specified, this stress will be at the yield point.

Proportional limit: the greatest stress at which a material is capable of sustaining the applied load without any deviation from the proportionality of stress to strain (Hooke's Law).

Modulus of elasticity: the ratio of stress to the corresponding strain below the proportional limit of the material. It is expressed in F/A . This is also known as Young's modulus. A modulus is a measure of the material's stiffness.

Ultimate strength: the maximum unit stress a material will withstand when subjected to an applied load in compression, tension, or shear.

Secant modulus: the ratio of the total stress to the corresponding strain at any specific point on the stress-strain curve.

The stress-strain diagram illustrated in **Fig. 10** is typical of that obtained in tension for a constant rate of loading. However, the curves obtained from other loading conditions, such as compression or shear, are quite similar in appearance.

The initial portion of the stress-strain curve between point A and C is linear and it follows Hooke's law, which states that for an elastic material the stress is proportional to the strain. The point C at which the actual curve deviates from the straight line is called the proportional limit, meaning that only up to this point is stress proportional to strain. The behavior of material below the proportional limit is elastic in nature and therefore the deformations are recoverable.

Fig. 10 A typical stress-strain curve [12].

Fig. 11 Relation between ductility and strength [12].

The area under the stress-strain curve is considered to be the toughness of the polymeric material. Fig. 11 illustrates the relation between ductility and strength.

The matrix material transmits the force to the fibers, which carry most of the applied force. The matrix also provides protection for the fiber surface and minimizes the diffusion of species such as oxygen or moisture that can degrade the mechanical properties of the fibers. The mechanical properties of FRPs are related to the mechanical properties and fractional volume of each phase, matrix and reinforcement. This is called the rule of mixture. By using the rule of mixture, the properties as well as the strength, the modulus of elasticity, the density, and the electrical and thermal conductivity are predictable. In addition, the rule of mixture is used to predict the modulus of elasticity when the fibers are continuous and unidirectional [13]. Parallel to the fibers, the modulus of elasticity may be as high as:

$$E_c = f_m E_m + f_f E_f \quad [1]$$

where f is the volume fraction and the subscripts m and f refer to the matrix and the fiber. Note that $f_m = 1 - f_f$.

However, when the applied stress is very large, the matrix begins to deform and the stress-strain curve is no longer linear as in Fig. 12. Since the matrix now contributes little to the stiffness of the composite, the modulus can be approximated by:

Fig. 12 The stress-strain curve for a fiber-reinforced composite [13].

Fig. 13 Different forms of IFF [14].

$$E_c = f_f E_f \quad [2]$$

Fig. 12 demonstrates that at low stresses (region i), the modulus of elasticity is given by the rule of mixtures. At higher stresses (region iii), the matrix deforms and the rule of mixture is no longer obeyed [13].

Attention must be paid to the fact that different combinations of stresses lead to different forms of Inter Fiber Fracture (IFF). This is of major importance since some forms of IFF are harmless for certain applications whereas other forms lead inevitably to structural failure [14] (**Fig. 13**).

Design properties

From the design standpoint, the most significant stress-strain properties can be categorized under three headings [11].

Strength

There are three strength values of interest:

- (1) The yield strength is the highest stress that the material can withstand without undergoing significant yielding.
- (2) The ultimate strength is the maximum value of stress that the material can withstand.
- (3) The fracture stress, if different from the ultimate stress, may be of interest. It is the value of the stress at fracture.

Stiffness

The stiffness of a material is basically the ratio of stress to strain. Stiffness is of interest primarily in the linearly elastic region; therefore, Young's modulus is the value used to represent the stiffness of a material.

Ductility

Materials that can undergo large strain before fracture are classified as ductile materials; those that fail at small values of strain are classified as brittle materials. Strictly speaking, the terms ductile and brittle refer to the mode of fracture, and a material like structural steel, which behaves in a ductile manner at room temperature, may exhibit brittle behavior at very low temperatures. Therefore, when we speak of a 'brittle material' or a 'ductile material', we are referring to the room temperature behavior of the material.

The two commonly used measures of ductility are the percentage of elongation and the percentage of reduction in the area at the section where fracture occurs (the area reduction is expressed as a percentage of the original area).

Factors affecting mechanical properties

Many factors must be considered when designing an FRP composite, including the length, diameter, orientation, amount and properties of the fibers, the matrix and the bonding between the fibers and the matrix.

Specimen size and specimen preparation

In the case of fiber length and diameter, it should be considered that fibers can be short, long, or even continuous. Their dimensions are often characterized by the aspect ratio of d/l where l is the fiber length and d is the diameter. Typical fibers have a diameter varying from 10 to 150 μm . The strength of the composite improves when the aspect ratio is large. Generally, the aspect ratio has to be superior to 10, which is considered to be the minimum aspect ratio value for good strength transmission for any reinforcement [15]. Fibers often fracture because of surface imperfections. Making the diameter as small as possible gives the fiber less surface area and, consequently, fewer flaws that might propagate during processing or under a load. A long fiber is preferable. The ends of a fiber carry less of the load than the remainder of the fiber, consequently, the fewer the ends, the higher the load ability of the fibers [13].

The process employed to prepare the specimens also has a significant effect. For example, injection molded specimens generally yield a higher tensile strength value than compression molded specimens. Machining usually lowers the tensile and elongation values because of the small irregularities introduced into the machine specimen. Another important factor affecting the test results is the location and size of the gate on the molded specimens. This is especially true in the case of glass-fiber-reinforced specimens. A large gate located on top of the tensile bar will orient the fibers parallel to the applied load, yielding higher tensile strength. A gate located on one side of the tensile bar will disperse the fiber in a random fashion. This effect is shown in Fig. 14 [12] and examples of composite sample configurations at different fiber orientation angles are shown in Fig. 15 [16].

The orientation of the fibers could also change the strength and stiffness of the composite. The reinforcing fibers may be introduced into the matrix in a number of orientations. Short, randomly oriented fibers having a small aspect ratio are easily introduced into the matrix and give relatively good isotropic behavior to the composite.

Fig. 14 The effect of fiberglass orientation [12].

Fig. 15 Examples of composite sample configurations at different fiber orientation angles for tensile testing (a) 0° (b) 45° (c) 90° , and (d) random [16].

Fig. 16 Effect of fiber orientation on the tensile strength of an FRP composite [13].

Long or even continuous unidirectional arrangements of fibers produce anisotropic properties, with particularly good strength and stiffness parallel to the fibers. These fibers are often designated as 0° , indicating that all of the fibers are aligned with the direction of the applied stress. However, unidirectional orientations provide poor properties if the load is perpendicular to the fibers as in Fig. 16 [13].

Fig. 17 Relationship between the composites' Young's modulus and fiber orientation angle (0° means along the fiber direction and 90° means perpendicular to the fiber direction) [17].

Fig. 18 The effect of temperature on tensile strength [12].

Fig. 16 shows that the greatest strength is obtained when the force is applied along the fibers and the least is when the force is applied perpendicular to the fibers [13].

In addition, the fiber orientation also effects the Young's modulus as in Fig. 17 [17].

From Fig. 17, it can be seen that the Young's modulus of the composites strongly depends on the fiber orientation angle. When the angle is 0° (loading along the fiber direction), the stiffness of the composites reaches its highest value. The lowest stiffness is when this angle is around 60° . After this angle, the composite's Young's modulus increases slightly with the rise of the fiber orientation angle.

Rate of straining

As the straining rate is increased, the tensile strength and modulus increase. However, the elongation is inversely proportional to the strain rate [12].

Fig. 19 Preparation of glass fiber with 45° orientation.

Fig. 20 Glass sheet cleaning.

Temperature

The tensile properties of some plastics change rapidly with a small change in temperature. Tensile strength and modulus are decreased while elongation is increased as the temperature increases. The effect of temperature on tensile strength is shown in [Fig. 18](#).

Materials and Methods

Preparation of Woven Fabric Glass Epoxy Composite Laminate by the Hand Layup Technique

The woven glass fibers were cut with 45° orientation as in [Fig. 19](#). A glass sheet was used at the top and bottom in order to obtain a good surface for the laminate. Initially, the glass sheet was cleaned 3 times to eliminate dust and avoid the sticking of the laminate after curing as in [Fig. 20](#). The fibers were stacked layer by layer upto 8 layers. A bonding agent (epoxy resin) was applied to create bonding between 8 layers of sheets, in the ratio of fiber:resin; 30:70. The resin was formed from two different chemicals. These were referred to as the 'epoxy' and the 'hardener'. The chemicals were mixed in the ratio of epoxy: hardener; 2:1. Each layer of the resin was poured onto the fiber uniformly to obtain the required bonding. The composites were then cured at room temperature overnight. The covering sheet (glass sheet) was placed and compressed as in [Fig. 21](#). After the curing process, the composites were

Fig. 21 Curing process.

Fig. 22 Sample cutting.

Fig. 23 Test specimens.

cut using a band saw with dimensions of 250 mm $\times$ 25 mm to the required size and shape according to ASTM D 3039/D 3039 M [18] as in Fig. 22. Thickness was also measured to calculate the cross-sectional area.

Mechanical Testing

The specimens were tabbed with sandpaper and were subsequently measured for gage length as in Fig. 23. The tensile properties of the composites were measured using a Galdabini Universal Testing Machine. Each tensile test was performed at a cross-head speed of 2 mm min⁻¹ on the specimens, until tensile failure was detected as in Fig. 24. Six specimens of sample were tested.

Fig. 24 Tensile testing fixture.

Fig. 25 Stress-strain curve of composite laminate with 45° orientation.

Data analysis

The load applied and the deflection were recorded. A stress and strain curve was plotted. The Young's modulus, the modulus of toughness (area under the stress-strain curve) and the percentage elongation at break point were also calculated as follows. The data was compared with the 60 and 90° orientation samples.

$$\sigma = F/A \quad [3]$$

where: σ =stress (Pa); F =load (N), and A =cross-sectional area (m^2)

$$\varepsilon = \Delta l/l \quad [4]$$

where: ε =strain; Δl =change in length (deformation), and l =gage length.

Results and Discussion

Effect of Fiber Orientation on Tensile Testing

Fig. 25 and **Table 2** illustrate the properties of the composite laminate of 45° orientation. Six specimens were tested and compared with the specimen without tab. A recent study found that the properties of specimens are affected by tabbing. More load is required for the fracture of the specimen without tab, and also more tensile strength and Young's modulus are obtained. Toughness is related to the area under the stress-strain curve. In order to be tough, a material must be both strong and ductile [12]. Therefore, the specimen with tab is stronger than the specimen without tab, because tab is required to prevent gripping damage during tensile testing [18].

Table 2 Comparison of properties of composite laminate 45° orientation between 'with tab' and 'without tab'

Properties	With tab	Without tab
Width (mm)	24.30	24.42
Thickness (mm)	2.68	2.62
Area ($E-05 \text{ m}^2$)	6.51	6.40
Gage length (mm)	160	160
Max load (KN)	6.78	7.15
Max deflection (mm)	5.96	4.99
Max stress (MPa); ultimate tensile strength (UTS)	104.25	112.711
Max strain (mm mm^{-1})	0.0372	0.0312
Young's modulus (Gpa)	4.516	5.081
Modulus of resilience (Kpa)	1.334	1.494
Modulus of toughness (Mpa)	2.12	1.93
Elongation at break (%)	3.71	3.12

**Fig. 26** Stress-strain curve of a composite laminate with 60° orientation.

Fig.s 26 and **27** show the stress-strain curves of composite laminates with 60° and 90° orientation, respectively. Based on ASTM D 3039/D 3039 M, the number of specimens for tensile testing is at least five per test condition, unless valid results can be obtained through the use of fewer specimens. In a recent study, at degrees of 60° and 90°, the number of specimens tested was more than five, but only two specimens of 60° and three specimens of 90° were tested until tensile failure was detected. Meanwhile other specimens lost from grip or tab were loosened due to not enough glue being used for tab, or the fixture of the specimen with the machine not being fastened properly. Other configurations that have reportedly been successfully have incorporated steel tabs or tabs made of the same material as is being tested [18].

Moreover, **Fig. 27** demonstrates that the tensile strength of composite laminate sample 3 decreased during testing (as marked with a black circle). This can be a result of the lamination stage, which used a hand layup technique. So air bubbles occurred during this stage or the matrix phase (resin) did not disperse as well. Therefore, to prevent air bubbles from forming, a rolling device should be used.

It can be seen from **Table 3**, **Fig.s 28** and **29** that: (1) the maximum load, the ultimate tensile strength (UTS), the Young's modulus, and the modulus of toughness are highest in the case of 90° orientation. On the other hand, the maximum load and ultimate tensile strength are lowest in the case of 60° orientation, and the Young's modulus and also the modulus of toughness are lowest in the case of 45° orientation; (2) the maximum deflection is highest in the case of 60° orientation and led to maximum strain and elongation at break.

According to theory, the highest tensile strength obtained should be a composite with 0° orientation and the lowest with 90° orientation. This is because composites with 0° orientation possess long and continuous glass fibers to resist and transfer the tensile force, whereas the other fiber orientation angles (30°, 45°, 60°, and 90°) contain short, broken and discontinuous fibers [13, 16, 19]. But a recent study found that the highest tensile strength was obtained when the composite had a 90° orientation, which is in contrast with the theory described. However, there were a few research studies that

Fig. 31 Tensile test failure codes/typical modes [18].

reported that the tensile strength will be affected by the resin content [20]. Since, in this study, a hand layup technique was used without a roller device for lamination, this may be the cause of the difference in resin content during the curing process even though the composite laminate was prepared using the same ratio of fiber: resin; 30:70. This subsequently had an effect on the tensile strength.

In addition, the theory of the relationship between the composites' Young's modulus and the fiber orientation angle indicates that the U-shaped dependency of the Young's modulus of the composites on the fiber orientation angle will be obtained when the angle is 0° (loading along fiber direction), and the stiffness of the composites then reaches its highest value. The lowest stiffness is when this angle is around 60° [17]. A recent study found that the lowest Young's modulus occurs in the case of 45° orientation. The result obtained is almost similar to the theory of the U-shape as shown in Fig. 29(b).

Failure Analysis

Fig. 30 demonstrates the failure of the specimens. Each specimen was tested until tensile failure was detected. It was found that some specimens fractured at the top, meanwhile some specimens fractured at the bottom. This may be affected by the different loads applied during manual fixing of the specimen with the instrument.

According to the tensile test failure codes as in Fig. 31, it can be concluded that there are two attributes of failure from this study – AGT and AGB – where A means the failure type is angle, G means the failure area is gage, T means the failure location is top, and B means the failure location is bottom.

Conclusion

In this work, woven fabric glass epoxy composite laminate was prepared using a hand layup technique and the effect of fiber orientation on the mechanical properties was investigated. The experiment found that:

(1) the maximum load, the ultimate tensile strength (UTS), the Young's modulus and the modulus of toughness are highest in the case of 90° orientation. On the other hand, the maximum load and the ultimate tensile strength are lowest in the case of 60° orientation, and the Young's modulus and also the modulus of toughness are lowest in the case of 45° orientation;

(2) the maximum deflection is highest in the case of 60° orientation and led to maximum strain and elongation at break. Therefore, to achieve the optimum property for future application, the manufacturing process should pay attention to the fiber orientation due to this being an important factor affecting the properties. From the design standpoint, the most significant properties can be categorized under the following three headings: strength, stiffness, and ductility.

Introduction

Hybrid composite materials were developed by the motivation of improving the imbalance properties of common homogeneous composite materials. From recent review done by Wu *et al.* [1] it was stated that hybrid composites can be considered to have positive hybrid effect on mechanical properties (e.g., failure strain, strength and impact properties) and fatigue strength resulted with improvement from its relative homogeneous composite. Previously, researches had been extensively investigated the mechanical properties and fatigue properties of different types of hybrid composites [1–4].

Carbon/Kevlar hybrid composite is one of hybrid composites that had been used widely in the commercial aircraft structures. It was proven in the previous works [5–7] that there were positive hybrid effect on its mechanical properties and fatigue behaviour. Although many studies had been done extensively on the mechanical properties of this hybrid composites at ambient temperature, investigations on the changes of these properties at low temperature are still lacking. Due to the weather condition, FRP composites applied in aircraft structures generally experience wide range of temperature changes during its operation [8,9]. Thus it is also necessary to identify the properties of these FRPs against the temperature changes to ensure its reliability to be exploited in the industry, especially the aircraft industry.

In non-ambient temperature, temperature changes can affect the materials' mechanical behaviours in many different ways such as thermoelasticity, displacement, strain, stress and other constitutive relations like elasticity related stresses or strain. Change in temperature generally will displace the materials' molecule structures by any general or relative motion and eventually will change the mechanical properties (stress distribution and strain) of the whole materials. These so called expansion and contraction in dimensions caused by the molecular bonds in materials to the changes of temperature is known as Coefficient of Thermal Expansion (CTE). The CTE value of a material presents how much strain it experiences for 1°C temperature change and if the material experience contraction instead of expansion, negative value of CTE will be obtained.

Due to its lower melting point, polymeric-based matrix is generally known as the most temperature-sensitive constituents in composite materials. With lowering of temperature, the energy of the molecular bonds decreased and leads to stiffening, resulting in increased hardness and brittleness. Similarly, reinforcing fibres also experience changes in molecular structures with change in environment temperature. Kevlar fibres showed expansion at fibre direction and contraction at transverse directions of the unit cells at low temperature [10–12]. In addition, it was also reported that Kevlar fibres's residual crystallinity, which was said to be closely related to the tensile modulus also changed to the changes of temperature [11]. Although the results reported that its residual crystallinity increases linearly as the temperature decreases, there was only a slight reduction of residual crystallinity between the ambient and 0°C temperature range, indicating that its tensile modulus might be lower at this temperature range. Even though the relationship between the residual crystallinity and tensile modulus was not reported in details as there was no experimental or analytical results discussed in this work, it was reported in work by Katogi *et al.* [13] that flexural strength and modulus of carbon composites increased as the crystallinity of its polypropylene matrix increased.

Regardless of the linear pattern of the individual matrices and fibres' dimension change to the temperature, the pattern in composites will not be in a linear manner. Non-linearity of expansion and contraction were found in several composite materials as reported by Reed and Golda [12]. Unidirectional CFRP and aramid FRP were generally will expand axially and contract transversely at low temperature. Meanwhile for matrices used in the composite materials reviewed, it contracted more than expansion and contraction experienced by the fibres at low temperature.

The big difference of expansion/contraction amount between the fibres and matrices at the same low temperature also can be represented as the mismatch of CTE. The larger mismatch of CTE at low temperature might cause the residual stresses at fibre-matrix interfaces to increase. Increased residual stresses then will possibly tend to enhance micro cracking in matrices and reduce the composite strength. This work then recommended using fibres with higher contraction rate like glass fibres for composite materials applied at low temperature range. Other than mismatch CTE induced residual stresses, composites mechanical behaviours at non-ambient temperature are also influenced by the thermal stresses [10,14]. As an example, Gates *et al.* [14] explained that total stress experienced by a UD composite laminate is the accumulation of both mechanical stresses and thermal stresses as shown in Eq. (1)

$$\begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{12} \end{Bmatrix} = [Q] \left[\begin{Bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{12} \end{Bmatrix} - \begin{Bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{12} \end{Bmatrix}^T \right] \quad (1)$$

In this equation, Q is the value of the stiffness of the matrix, ε is the normal strain and thermal strain can be calculated from the equation below. From the equation, normal strain ε and shear strain γ can be obtained from the CTE values, α . The ΔT value in this equation is the temperature difference of the environmental testing temperature with the environmental temperature of the laminate at stress free condition during cure. This equation showed that larger value of CTE and temperature difference ΔT will result in a larger thermal strain.

$$\begin{Bmatrix} \varepsilon_{11}^T \\ \varepsilon_{22}^T \\ \gamma_{12}^T \end{Bmatrix} = \begin{Bmatrix} \alpha_1 \\ \alpha_2 \\ 0 \end{Bmatrix} \Delta T \quad (2)$$

It was also reported that nonlinear CTEs were obtained for composite materials at low temperatures, indicating that the stiffness and strength also varied with indiscernible pattern. An example is the work done by Gaitonde & Lowson [15] that showed the CTE value of carbon fibre composite (AS4/PEEK) can be plotted as 'U shape', where the CTE values are higher at very low temperature (-140°C) and at higher temperature (40°C). The lowest CTE was recorded at -80°C where it became brittle at this stage, but the composite materials went back to ductile state when the temperature kept decreasing. However, this non-linear pattern was only found in CFRP with unidirectional and angle-ply fibre arrangement. For CFRP with transverse fibre arrangement, its CTE value was found to be higher and changing linearly to the changes of temperature. It was concluded that the high expansion of the composite structures with transverse fibre arrangement was highly influenced by the matrix. Thus, it was recommended to conduct any low temperature mechanical testing at all temperature levels intended but with smaller range. Hence, the selection of temperature in this work lies within a small range between the ambient to -10°C whereas most reported works were conducted in the cryogenic region.

The mismatch of expansion and contraction between the fibres and matrices in composite structures also will significantly affect its mechanical properties under various stress conditions. From the results obtained by Hartwig & Knaak [10] compared to glass fibre composites, aramid fibres experienced larger contraction than its polymer matrix and caused the fibre-matrix interfacial bonding to decrease. At low temperature, the radial or transverse hydrogen bond in aramid fibres became stronger, reduced the adhesion and interfacial friction, and resulted with lower transverse and interlaminar shear strength compared to carbon and glass composite materials.

Aside from thermally induced effects on the mechanical behaviour, the configuration and arrangement of reinforcing fibre play a large role in influencing the tensile behaviour whereas the matrix has a dominant role in compressive behaviour. Reed and Golda [12] had previously reported on the positive effects on the tensile strength and modulus of unidirectional CFRP laminates at cryogenic temperatures. Much later, Sánchez-Sáez *et al.* [16] conducted tensile tests at discrete temperatures ranging from ambient to -150°C and showed that the tensile modulus slightly decreased for a cross-ply unidirectional CFRP but increased for a quasi-isotropic laminate. However, both configurations showed increase in tensile strength with decrease in temperature. Significant reduction in the failure strains at low temperatures was also reported. Their work concluded that the stacking arrangement was found to strongly affect the mechanical response. Meanwhile, Majerski *et al.* [8] reported the opposite where a decrease in tensile strength and increase of modulus for UD laminates at low temperatures was observed.

All the contradicting studies showed that the factors that influence the mechanical behaviour of composite materials at low temperature and their interactions cannot be readily estimated and therefore experimental investigation becomes necessary. The scope of the current work is on the investigations of the changes of tensile properties of woven intraply carbon/Kevlar hybrid composite at low temperature ranging from ambient to -10°C . A near ambient and small range of temperatures are selected to reduce the risk of encountering non-linear effects of thermal mismatch and relations between the temperature and tensile properties. The results were presented in tensile strength, tensile modulus and failure strain.

Methodology

The experimental work started with the preparations of the samples firstly by fabricating the composite laminates, followed by cutting and tabbing process as per the ASTM D3039-00. To characterize the properties of the fabricated hybrid composite materials, density test were conducted to determine the volume fractions of each of its constituents. Tensile test was conducted firstly at ambient temperature for obtaining ultimate tensile strength (UTS) and tensile modulus and failure strain of hybrid composites. Then tensile test was carried at lower temperature and properties were analyzed and compared to the data obtained from the tests done at ambient temperature.

Composite Plate Fabrication Using Vacuum Infusion (VI) Method

Vacuum Infusion (VI) process was used due to lower cost and ability to produce high quality composite materials that are suitable to be used in aircraft structures. The fabrication process of hybrid composite laminate started with preparing the materials and tools. Consistent with the application of the composite, which is to be used in mechanical testing, the right dimension of composite and required thickness are very important to be determined first. The details of the process and precautions done during fabricating woven carbon/Kevlar reinforced epoxy hybrid composite laminates also will be discussed in the next sub-topics.

Flexural strength	84.81 Mpa
Flexural modulus	2.96 Gpa
Compressive strength	72.39 Mpa
Heat deflection	53°C

Materials

(1) Reinforcing fibres

Fibres used in this work are composed of two different fibres, which are 3K carbon fibres and Kevlar-29. These two fibres were weaved together in one cloth, where carbon fibres as the warp and Kevlar fibres as the weft. One unit cell is the smallest repeating pattern in the woven cloth, where one unit cell of this woven cloth contains two unit cells of carbon fibre and two unit cells of Kevlar fibre. The area of one unit cell is approximately 15.75 mm² as shown in Fig. 1. The total fibre volume fraction, V_f is 60% and carbon fibre and Kevlar fibre ratio is 4:5. The thickness of the woven cloth is approximately 0.26 mm. For fabricating the composite plate, ten plies of fibre cloths with dimension of 300 mm × 500 mm and 350 mm and 500 mm were used.

(2) Matrix

The matrix of the composite was made of EpoxAmite 100 base epoxy resin, which a type of resin that can be cured in the room temperature. To accommodate the flow of resin and effectively infusing the fibre cloth, a slow hardening resin, the 103 type with low viscosity was used. The specifications of the resin can be found in Table 1, as given from the product's manufacturer. Slow hardener was chosen because of its longer curing time, which is 55 min. Longer time for the resin to cure allows it to be distributed uniformly during the infusion process. The hardener was used with mix ratio by weight of 100: 24 (resin:hardener).

Vacuum infusion manufacturing process

Vacuum infusion is utilized for the fabrication of the carbon/Kevlar reinforced epoxy hybrid composites. This process was chosen due to its ability to distribute the resin evenly without any excessive use of resin and work force. However, the drawbacks of this process are too many tools needed and without a proper control on the infusion pressure, decreased flow of resin will result in accumulation of resin at the center part of fibre lay-up. The overall flow of resin in vacuum infusion is visualized in a schematic

Fig. 2 Schematic diagram of the resin flow in a vacuum infusion process.

Fig. 3 Schematic diagram of arrangement of the open mold.

Fig. 4 Composite laminates dimensions and sample's cutting direction for tests at ambient temperature.

diagram in Fig. 2. The resin flow started from the resin pot to the open mold prepared through an inlet tube. The resin will flow the other end of open mold, where an outlet tube connecting the mold to the resin trap and vacuum pump.

The fabricating process was started with preparing the open mold for the composite plate. The arrangement of the open mold can be referred to the diagram showed in Fig. 3. Fibre layers were cut based on the required sample sizes stated in ASTM D303900 (25 mm × 250 mm) for both tensile and fatigue testing. Composite laminates sizes were optimized based on the sample's dimension and its fibre direction to avoid excessive waste of fibres as shown in Fig. 4.

To prevent the finished composite laminate to be bonded on the fabricating surface, moulding wax was applied at least three times before laying up the fibre layers. At both ends of the fibre layers were placed spiral tubes (Fig. 5(a)). These tubes were used to ensure that the resin enters and wet the fibre layers not only at one spot but also through the whole length of fibre layers. Then, a peel ply that works as the barrier between the laminate was laid up first on the fibre cloth (Fig. 5(b)). This ply allows the finished composite laminate to be peeled off from the vacuum bag easily. It is very important to make sure that the peel ply used is big enough to cover the fibre cloths and spiral tubes. A mesh sheet, which works to accelerate the resin flow and distribute the resin evenly inside the fibre cloths then placed on the peel ply. Finally, the laminate was covered and sealed with vacuum bag tightly (Fig. 5(c)). The outlet tube connected to the vacuum pump and this is where the vacuum pressure will be applied during the fabrication process (Fig. 5(d)).

After the vacuum bag was tightly sealed, resin infusion process will be started by turning on the vacuum pump to check any occurrence of leaks. The leaks should be checked using the leak detector. The resin infusion process was initiated with low pressure, around -30 kPa for several minutes. This step was done to observe any leaks and also to remove any air trap between the fibre layers.

Fig. 5 Overall process of fabricating composite laminate by Vacuum Infusion method.

Then, the pressure was increased to -60 kPa and resin proceeded to infuse the cloth from the inlet tube. When the resin was already distributed midway of the fibre cloths, the pressure again was increased to -80 kPa and the resin gradually will flow until it reach the spiral tube at the other end of the fibre cloths (**Fig. 5(e)**). During this time, the resin flow is much slower and the pressure is increased to -100 kPa. When all the resin was completely infused into the fibre clothes, both inlet and outlet tube of the laminate were closed tightly and the laminates were set to cure in room temperature for 24 h in vacuumed condition.

After the composite laminate was fully cured, vacuum bag, peel-ply and mesh sheet were removed and the finished products were weighed whereby the final weight of the composite laminate is used to calculate the weight fraction and volume fraction of each constituents of the composite (fibres and matrix).

Tensile Testing

For tensile testing, the composite plates were cut into rectangular coupon shape with dimensions of 250 mm in length and 25 mm in width, according to the ASTM D3039. The thickness of all the specimens ranges from 2.0 to 2.3 mm. To avoid any slipping occurrence or failures at the grip area, 50 mm long emery cloths were attached at both ends of the top and bottom surface of the specimen. Tensile tests were conducted in accordance to ASTM D3039 using the MTS 810 universal tensile machine with the

Fig. 6 The overall design of the cooling chamber system.

Table 2 Tensile properties of woven intraply carbon/Kevlar hybrid composites at ambient and low temperature

Test temperature [$^{\circ}\text{C}$]	Ultimate tensile strength, UTS [Mpa]	Tensile modulus, E [Gpa]	Poisson's ratio	Elongation at break (mm)
Ambient	554 ± 26.9	54.95 ± 1.67	0.1	6.31 ± 0.1
0	627 ± 3.19 (+ 13.2%)	50.73 ± 0.4 (− 7.7%)	0.1	4.2 ± 0.1 (− 33.4%)
− 5	652.73 ± 15.5 (+ 17.8%)	55.51 ± 1.03 (+ 1.0%)	0.1	4.14 ± 0.5 (− 34.4%)
− 10	592.23 ± 15.61 (+ 6.9%)	53.32 ± 1.11 (− 3.0%)	0.1	3.87 ± 0.2 (− 38.7%)

crosshead speed of 2 mm/min. Kyowa foil-type strain gauges were employed to measure the axial and lateral strain. For sub-ambient tensile tests, a customized cooling chamber was designed to provide the cool ambience needed (Fig. 6). The cooling chamber was designed with a through hole in the middle and cooling coils placed around the cooling box. The specimens were gripped and placed inside the through hole, which makes only the gage section of the specimens will be cooled inside the cooling chamber. Cooling coils were placed at both sides and back part of the cooling box to give the optimized cooling rate. Ventilation fans that placed at both side play the roles to circulate the air inside the cooling box and help the temperature of the air to be constant longer. The size of the cooling box was made to accommodate enough space between the two grips so that it will not collide with the grips during the cyclic loading. The cold environment was set to three temperatures, which were 0°C , -5°C and -10°C .

Results and Discussions

The mechanical properties obtained from the tensile tests at ambient and low temperatures was tabulated in Table 2 and compared with the materials' properties obtained from the tests done at ambient temperature. From the previous section, most reported works are on unidirectional composite laminates and conflicting findings have been reported. However, generally the strength increases while the modulus decreases due to reduced ductility.

From the results obtained, the tensile strength of the hybrid composite increased at all low temperature tested. Change of tensile strength and tensile modulus at ambient and low temperatures is shown in Fig. 7. This result was found to be in contrary with the results obtained in the previous work by Majerski [8] but in agreement with those obtained from reference [16]. Majerski [8] reported that as the matrix became brittle, the UTS of UID carbon fibre/epoxy composite decreased significantly at sub-zero temperature. However, the changes in the pattern is indiscernible as the increment of tensile strength at lowest temperature (-10°C) showed the least value compared to the other temperature but this could be due to within the bounds of experimental measurement uncertainties. These results showed that there is possibility that extended deformations of the brittle matrix took

Fig. 7 Change of tensile strength and tensile modulus at ambient and low temperatures.

place at this state, thus resulting with reduced strength. The tensile modulus at 0°C, was found to be reduced significantly, which was 7.7% lower than its tensile modulus at ambient temperature. However, no significant changes were found for tensile modulus of the samples tested at -5°C and -10°C . On the other hand, composites' total elongation reduction can be seen for samples tested at all three different temperatures and the reduction increased as the temperature decreased.

Reduction of tensile modulus might be caused by the mismatch of thermal coefficient between fibres and matrix in the hybrid composite at lower temperature. This non-linear change of tensile modulus, which caused by the expansion and contraction of fibres at low temperature also had been reported to be found in several CFRP and Kevlar FRP [9]. In addition, Kevlar fibres crystallinity at low temperature might affect its tensile modulus as reported by Iyer *et al.* [11]. The results showed that residual crystallinity of Kevlar fibres was slightly reduced at 0°C and started to increase at sub-zero temperature (minimum -100°C). Thus, it explained that decreased crystallinity at 0°C caused the reduction of tensile modulus of hybrid composites investigated in this work. These results showed that colder environments generally delayed the softening process of the matrix and caused the composite materials to be able to sustain higher load. However, as the environmental temperature gets colder than 0°C, the matrix became more stiff and brittle. Stiffer matrix caused the composite materials to be more susceptible to abrupt failure, resulting with reduced strength. This brittle behaviour also can be seen from the high reduction of strain failure obtained from the test.

Conclusion

As a conclusion, intra-ply woven carbon/Kevlar hybrid composites have better tensile strength at near ambient low temperatures within a range of ambient to -10°C . Change of tensile modulus in hybrid composite to low temperature environment showed an indiscernible pattern, which might be caused by the mismatch shrinkage properties of the fibres and the matrix. On the contrary, the failure strain was seen to be decreased as the temperature decreased, showing that regardless of high strength it could sustain, stiffer matrix might affect the hybrid composite's impact resistance properties.

Introduction

FDM process has emerged as a revolution in the field of additive manufacturing (AM) where complex 3D structures can be fabricated quickly, without any assistance of conventional tooling, even at a low cost. FDM can generally be used for making models, prototypes, and also for batch production. The process starts from the identification of benchmark [1]. The FDM printed parts are also used for design validation, serviceability, and medical applications [2]. The reinforced ceramics in polymeric matrix have shown significant advantages [3,4]. Fig. 1 shows commonly used tests for thermal characterization of polymeric based composites. The reported literature highlights that the thermal stability of thermoplastic composites increased by increasing proportion of reinforcement, which needs to be explored systematically [5–8].

Sawpan *et al.* [8] conducted dynamic mechanical analysis (DMA) on glass fiber reinforced polymer to study the aging effect on its application, performance, and life time. The DMA detects the molecular motion changes in polymer composites with the variation of temperature. So far, mechanical characterization of polymer composite material is essential to choose the materials over traditional materials for numerous types of applications [9]. Essabir *et al.* [10] investigated the tensile and rheological properties of fibers reinforced composite, to realize the effect of fiber contents, frequency, temperature, and compatibilizer on the composite properties. Shanmugam and Thiruchitrambalam [11] studied the viscoelastic behavior of treated jute fiber and palm leaf stalk fiber reinforced in unsaturated polyester matrix. It has been observed that with the increase of fiber contents storage and loss modulus were enhanced and thus increases in both static and dynamic mechanical properties were observed.

The DMA provides information on polymeric material in dynamic state and is generally used to determine the stiffness and damping property of the material. The $\tan\delta$, (ratio of storage/loss modulus), is used as an estimate for damping properties [12]. Kumar *et al.* [13] reported the characterization of treated coconut sheath fiber reinforced epoxy composite (TCSE) and untreated (raw) coconut sheath fiber reinforced epoxy composite (UTCSE). The study concluded that the TCSE composite material possesses higher thermal stability and mechanical strength as compared with UTCSE. The DMA results indicate that the $\tan\delta$ curve of TCSE shifts toward higher temperature and lower peak as compared with UTCSE. This indicates that TCSE composite material has less damping effect and better load bearing capacity. Das and Satapathy [14] conducted DMA analysis on polypropylene (PP)/cenosphere based composite material and revealed that energy dissipation ability and storage modulus of 10 wt% of cenosphere composite material enhanced as compared with soft PP- phase. Stark [15] demonstrated the correlation of DMA and DSC results of carbon fiber fabric impregnated with reactive epoxy resin and indications were found for gelation and vitrification (transformation of a substance into glass). Jakobsen *et al.* [16] investigated the change in Young's modulus during the isothermal curing of chopped strand mat E glass/epoxy composite. In another study storage/loss modulus and glass transition temperature of fly ash and polyuria composites were increased and as the fly ash contents increased [17].

Ornaghi *et al.* [18] outlined the properties of glass hybrid composites through DMA testing. It was concluded that storage/loss modulus increased with the higher glass loading and overall fiber volume. Cho and Bahadur outlined DMA analysis on polyphenylenesulfide composites reinforced with carbon nanofiber [19]. No significant effect on the damping properties was observed with the reinforcement. Brostow and Lobland [20] established a connection between brittleness and wear of polymeric materials by DMA and sliding wear test. They developed a formula that predicts the percentage recovery in sliding wear from the brittleness of material. Sa'ude *et al.* [21] performed DMA of ABS material reinforced with copper and concluded that storage modulus and $\tan\delta$ increased proportional with the loading of copper. Arivazhagan and Masood [22] demonstrated the DMA results under the influence of temperature and

frequency of ABS specimens fabricated on FDM by varying input parameters such as raster angle and width and built style. The study highlights that loss modulus increases with temperature while viscosity decreases with temperature.

In this work, the step-by-step procedure for preparing Nylon6-Al-Al₂O₃ feedstock filament, in place of commercial ABS material, has been presented for FDM. The viscoelastic properties were also studied by DMA analysis.

Development of Composite Material Feedstock Filament

The detailed experimental study has been executed at Manufacturing Research Lab, GNDEC, Ludhiana, India for the development of this composite material, so that the application domain of FDM process can be increased. The Fig. 2 shows the feedstock filament development process.

For this case study E-35 grade (extrusion grade) Nylon 6 was selected as a matrix material. The material was procured from local market of average particle size 4–5 mm and milled to 500–800 µm with cryogenic milling at – 96°C. Commercially pure aluminum metal (Al) of 325 mesh size and aluminum oxide (Al₂O₃) of 100 mesh size were selected as reinforcement. The flow properties of thermoplastic composites are strongly influenced with reinforcement of fillers [23,24]. In this study, 10 observations were recorded for each composition/proportion (see Table 1) and the average value was selected for further processing. This limits the practical levels of reinforcement in the thermoplastic polymers.

As observed from Table 1, MFI of virgin ABS is 2.415 g/10 min and virgin Nylon 6 is 10.61 g/10 min. It has been observed that by 40% reinforcement of Al powder, its MFI is 3.975 g/10 min and by 50% reinforcement it reduces to 2.375 g/10 min. Similarly, for Al₂O₃, it is more suitable if the loading remains less than 40%. Finally in this study 40% reinforcement of filler materials in Nylon 6 was kept as fixed.

The various ingredients of composite material were heated in vacuum oven to 55°C for 9 h at perfect vacuum conditions. The reinforcement in polymer matrix was mixed in tumbler mixture at 200 rpm for 2 h.

Filament Fabrication with Extrusion Process

Flow characterization

For preparing spoolable material in form of feedstock, having required consistent diameter, the processing conditions of new filament material can be controlled, by deliberately selecting the contents of binder and fillers materials [24–27]. It has been reported that the reinforcement in E-35 Nylon 6 results in modification of material morphology [23,28–30]. Fig. 3(a) shows the setup with a cylinder (with

temperature controlled circuit), piston, weights, and capillary die fitted at the bottom. The test has been conducted by maintaining cylinder temperature at 230°C and weight 3.8 Kg. **Fig. 3(b)** shows a pictorial view of the MFI tester. For each composition an average of minimum 10 observations were recorded. **Fig. 4** shows MFI values with reinforcement (of Al/ Al_2O_3) in various proportions.

Table 2 summarizes the proportions (by weight) of compositions/proportions. Based upon **Table 2**, MFI values are shown in **Fig. 5**. It has been observed that with increase of large particle sized (100 mesh) Al_2O_3 particles and decrease of small particle sized (325 mesh) Al in composition/proportion of polymeric composite, the MFI decreases. Moreover Al_2O_3 is ceramic material and its surface is rough, which may resist the particle mobility in the composite matrix.

Fabrication of filament with extrusion process

The actual single screw extrusion process is shown in **Fig. 6**. Further, **Table 3** shows the specifications of single screw extrusion process used in the present study. The critical input parameters for extrusion process are screw speed, exit die temperature, speed of take up unit, temperature of water tank, screw barrel temperature, and die nozzle diameter. Initially, the trials were performed and one set of parameters is selected that gives favorable responses such as uniform distribution of filler materials, desired filament diameter with minimum deviation and strength. **Table 4** shows input parameters for screw extrusion.

Inspection of feedstock filament

The qualification of newly processed feedstock filament for FDM process relies on various parameters such as material processing conditions required for fabrication of the filament, homogenous particle inclusion of filler in binder material, flow/rheological

Fig. 5 MFI of various compositions/proportions.

Fig. 6 3D view of extrusion process.

Table 3 Screw extruder specifications

and adhesion characteristics of constituents. It should be noted that the fabricated filaments (Fig. 7(a)) were stored in a dry place, to prevent moisture from the atmosphere. The visual inspection of the filament diameter was performed with digital micrometer (see Fig. 7(b)). Finally, filament within the diameter range of 1.75 ± 0.03 mm was successfully fabricated.

Mechanical (Tensile) testing of feedstock

The tensile strength of newly prepared feedstock filaments was checked as per ASTM-638 standard. Fig. 8(a) shows standard dimensions of tensile testing sample. Fig. 8(b–c) shows the pictorial view of specimen before and after testing. For this testing, 5 samples from each specimen were measured and average value has been reported in Table 5.

3D printing on FDM setup

For this study a u-PrintSE (Stratasys, USA) commercial FDM setup has been used. The wires of different compositions/proportions (as per Table 2) were run successfully on FDM. It should be noted that no buckling of wire was observed during plunging of filament, which indicates that the material is strong enough to force the material through the nozzle. However, it was also observed that the FDM nozzle got choked during the fabrication of parts (see Fig. 9). With increase in proportion of Al_2O_3 , the material gets clotted and it becomes difficult to pass through the liquefier head nozzle. Secondly, the increase of Al_2O_3 content in matrix causes increase in flow resistance. Since Al has self-lubricating properties and with the increase in its contents, it does not cause an abrasion effect on nozzle. Fig. 10 shows FDM printed parts.

Dynamic mechanical analysis

The DMA provides information on polymeric material in dynamic state and generally is used to determine the stiffness and damping behavior of the material [31]. The specimens for DMA analysis were fabricated with developed alternative material feedstock filaments on FDM setup. The rectangular shaped samples of $20 \times 9.5 \times 1.75$ mm for DMA analysis were prepared with solid density mode having raster angle $45^\circ/45^\circ$ (see Fig. 11).

The measurements for viscoelastic properties of developed composite materials and ABS material test specimens have been carried out in three-point bending mode. The tests were performed at a fixed frequency of 1 Hz and heating rate was $2^\circ\text{C}/\text{min}$ with a maximum dynamic force of 10 N. The specimens were initially dried in a vacuum oven at a temperature of 50°C for 8 h. The characterization includes storage modulus, loss modulus, and $\tan\delta$ for qualitatively and quantitatively investigating the effect of reinforcement in Nylon 6 matrix. Additionally, study highlights the shift of glass transition temperature and stiffness of composite materials.

Fig. 11 FDM printed samples for DMA.

Discussion

Rheological Properties

The flow behavior study of selected compositions of Nylon 6-Al-Al₂O₃ was recorded as per ASTM D1238-73 standard. This was done to investigate the flow rate at processing temperature in extrusion liquefier head of FDM. It has been pointed out that the presence of filler material in the matrix of Nylon 6 increases its viscosity as compared with virgin Nylon 6. Moreover, viscosity also increases with an increase to the particle size of filler materials. The MFI value of Al and Al₂O₃ was plotted on weight percentage loading scale as shown in Fig. 4. The curve illustrates that, in Nylon 6 matrix, the loading for Al metal is possible up to 45% and in case of Al₂O₃, it is limited to 40%. These comparative results can predict the flow behavior of newly developed material and this data helps to select the composition most suitable for FDM. The reason is that this composition can be processed in same conditions as ABS material has during the processing in FDM system. It has been depicted from Fig. 5 that composition “C” has high MFI value (2.31 g/10 min) and composition A has the least MFI value (2.19 g/10 min). The flow behavior of composition “C” is almost the same as the ABS material has, under the same temperature and pressure conditions (ASTM D1238-73). If the flow rate increases past the desired value it causes improper building of the part model and adversely effects the surface texture/finish.

Tensile Properties

It has been realized that as the proportion and size of filler material in polymeric matrix increase, mechanical strength starts decreasing [13–15]. The effect of reinforced material in polymeric matrix on Young’s modulus is highlighted in Table 5. The result shows that Young’s modulus and tensile strength of newly developed materials are less than ABS material but its percentage elongation is more. This is mainly attributed to the weak interaction of metallic material with polymeric materials and formation of voids around metal particles inside the polymeric structure. The Young’s modulus and tensile strength have high values for ABS but its results show slight decrease in values for composite materials. Among selected compositions it shows increase in value with increase in Al content. Moreover, it should be noted that Al₂O₃ particle size is larger than Al metal. The elongation at break also shows significant change and increase with increase in filler content and particle size. It was estimated from the results that tensile strength of alternative material (composition “C”) filament has slightly lesser value than standard ABS filament but with this composition, no buckling of filament takes place at the entrance of extrusion liquefier head of the FDM system during 3D printing. Moreover the tensile strength decreases with the increase in weight proportions of Al₂O₃ particles. This is mainly attributed to the poor compatibility of Al₂O₃ material with binder material (due to its abrasive nature). The feedstock filaments of composition “A” and “B” showed frequent buckling. This is due to poor mechanical properties and it causes nozzle chocking during part production process. Finally, tensile testing of filament successfully determined the suitability/compatibility of alternative material filament for the FDM system.

Dynamic Mechanical Analysis

3.3.1 Viscoelastic behavior of composite materials

The viscoelastic behavior of three compositions of Nylon6-Al-Al₂O₃ was studied to investigate the change in glass transition temperature and stiffness of material at processing temperature in the liquefier head of the FDM system. The parameters such as storage modulus characterize the stiffness, loss modulus highlights the energy dissipated in one loading cycle, and loss factor ($\tan \delta$) represents the internal resistance or mechanical damping of the polymeric based materials.

Storage modulus (E')

The variations of storage modulus with temperature for composition A, B, and C are shown in Fig. 12. The higher value of storage modulus for composition C is due to the increase in intermolecular bonding resulting from the presence of larger weight % proportion of Al than Al₂O₃ in Nylon 6 matrix (as already mentioned, composition C contains 30% Al and 10% Al₂O₃ particles). Moreover, average particle size of Al and Al₂O₃ are 50 μm and 150 μm , respectively. Due to the large particle size of Al₂O₃, the increase of its weight % proportions of reinforcement in Nylon 6 matrix causes poor interfacial bonding as in the case of composition A and B. In addition to the above, Al metal has a self-lubricating property and higher thermal conductivity than

Fig. 12 Storage modulus curves vs. temperature.

Al_2O_3 . The higher reinforcement of Al causes better heat and stress transfer and retains better matrix adhesion. The higher value of storage modulus exhibits high stiffness, which shows that composition C has high stiffness as compared with composition A and B. It is noteworthy that the increase in storage modulus due to filler reinforcement is more noticeable in the rubbery region than the glassy region as compared with ABS material. As the storage modulus indicates the capacity of material to store the input mechanical energy, it decreases with the increase of temperature [25]. The storage modulus is generally used for determining elastic properties of a polymeric based material. The curves show that, initially at low temperature, the storage modulus has high value and with the increase of temperature its value decreases gradually. In the intermediate region of the curves, the transition from the glassy state or energy elastic state to rubbery state or entropy elastic state occurs. This region indicates the onset of chain mobility [25]. This trend remains the same for all the compositions and is due to reinforcement of filler materials in the matrix. At elevated temperature, the storage modulus drops, which exhibits loss of stiffness. Among various compositions, composition C has maximum value of storage modulus in rubbery region compared with other composites.

Loss modulus (E'')

The loss modulus highlights the viscous properties of a polymeric based material and represents energy lost as heat or dissipated during one cyclic load. Typical loss modulus curves of the abovementioned compositions as a function of temperature are illustrated in Fig. 13. It should be noted that loss modulus was approximately steady at low temperature and rises to peak value at the onset temperature, which indicates the maximum heat dissipated per unit deformation [9]. The loss modulus of composition A is higher followed by composition B and C. There are two explanations for the change in peaks of loss modulus with the variation in weight proportions of fillers. First, the spherical shape of filler materials can enhance the energy dissipation under the influence of dynamic load [18]. Secondly, the polymer metal slippage or filler particle–particle slippage are resisted at low temperature due to the difference of coefficient of thermal expansion of polymer and fillers. The particle–particle slippage dissipated more heat. As the amount Al_2O_3 in Nylon 6 matrix increases, the peak values of loss modulus increases. The high peak value of loss modulus indicates that the intermolecular bonding is destroyed [9]. Fig. 13 shows the effect of type of filler and amount of filler are found to influence more on the value of loss modulus above the temperature of high peak value [12]. The curve become broadens after peak value, which indicates the difference in physical state of matrix surrounding the filler materials (Al and Al_2O_3). The trend remains the same for all the compositions.

Assessment of Loss factor ($\tan \delta$)

The $\tan \delta$ (ratio of E''/E' as per ISO 6721-1 standard) versus temperature variations for the proportions A, B, and C have been recorded (Fig. 14). A high value of loss factor of a polymeric material signifies nonelastic strain component. The DMA determines not only damping or loss modulus, but is also suitable for glass transition temperature (T_g) measurements. As the change in modulus under the influence of temperature is much more noticeable in DMA than other techniques such as differential scanning calorimeter (DSC), so it is more suitable for T_g measurements. Although T_g can be evaluated from the peaks of loss factor and loss modulus it is easy to measure from the peak of loss factor (ASTM D 4065-2001). The glass transition temperature (T_g), for proportions A, B, and C was observed as 82.5°C, 87.6°C, and 93.5°C respectively. The $\tan \delta$ results highlight that the composition/proportion C has high stiffness followed by composition B and A, but all are acceptable for running on commercial FDM. It was observed while printing of samples for DMA that feedstock filaments prepared with composition/proportion B and C run

Fig. 13 Loss modulus curves vs. temperature.

Fig. 14 Tan δ curves vs. temperature.

successfully without buckling in the FDM head. Whereas in composition/proportion A, the material buckled during the processing on FDM. The reason is due to large particle size and amount of Al_2O_3 filler particles in matrix. The reinforcement of filler material reduces the peak of tan δ curve [25]. With the filler reinforcement in Nylon 6 matrix, tan δ value decreases and T_g shows a shift toward higher value. The shifting of T_g toward higher temperatures indicates the decreased mobility of the chains with the reinforcement of fillers. The lowering of tan δ value indicates the improvement in interfacial bonding within the alternative material matrix [26,27]. So, it is ascertained that the alternative material "proportion C" has more stiffness and glass transition temperature than the proportions A and B.

Viscoelastic behavior of ABS material

Fig. 15 shows storage loss modulus and loss factor for ABS. As explained above, in the low temperature region, the material is in glassy state. However, in this region ABS material has storage modulus value less than alternative composite materials and this difference remains throughout the experimentation. In the transition region, the curve shows a rapid decrease in storage modulus to a constant value with the increase of temperature but composite material shows a gradual decrease in its value. This result indicates that ABS material has less stiffness than composite materials. The loss modulus and loss factor curves of ABS material

Fig. 15 DMA curves of ABS material.

exhibited higher peak value compared with those of composite materials. At temperature below glass transition, ABS material has lower loss modulus than those of composite materials and the intensity of the corresponding peak is also lower. For ABS, the glass transition temperature corresponding to $\tan \delta$ peak is 108°C and its peak value is 0.228, which is higher than composite materials. This is another reason that highlights low stiffness due to higher molecular mobility in ABS material.

From the above discussion it is realized that the composite materials possess better dynamic mechanical properties than standard ABS material.

Conclusions and Outlook

The experimental outputs are summarized as follows:

- (1) An alternate thermoplastic composite feedstock filament comprising of Nylon 6- Al_2O_3 has been successfully prepared for FDM. Based upon MFI analysis, 40% reinforcement in Nylon 6 matrix was established as a better solution in this case study.
- (2) Further for 40% reinforcement in Nylon 6 matrix, three proportions (A/B/C) were compared for tensile properties. The results of study suggests that the tensile strength of proportions A, B, and C are 64%, 53%, 28% poorer than ABS material, whereas tensile modulus is 2.7%, 2.1%, 1.5% lower than ABS material.
- (3) DMA of composition/proportion A, B, and C was performed and found better than ABS. In this case study the storage modulus for different selected compositions/proportions of reinforcements increases with the increase of filler amount in the Nylon 6. This resulted in a shift of glass transition temperature (toward the higher side). The increase of storage modulus highlights the good interfacial adhesion between polymer filler particles. Among various compositions, composition C has a rigid matrix.
- (4) The loss modulus curves, which are indicative of the dissipated energy (heat or stress) under cyclic load, were found to be shifted to higher position with the increase in Al_2O_3 content in the matrix. It has been observed that the composition/proportion A has the highest peak value followed by compositions B and C.
- (5) The glass transition temperature shifted toward the higher side with reinforcement of filler material in the matrix. This is because of constraints imposed on the mobility of molecules within the matrix. In case of composition C, the $\tan \delta$ curve shows a large shift toward the right side of the graph, which indicates the evidence of good interfacial bonding. $\tan \delta$ was found to be the lowest peak for composition C compared with compositions B and A.

Hydroxyapatite Based Polymer Composites for Regenerative Medicine Applications

Luis J del Valle and Jordi Puiggali, Chemical Engineering Department, Polytechnic University of Catalonia, Barcelona, Spain

© 2021 Elsevier Inc. All rights reserved.

Introduction

Tissue engineering comprises a set of methods focused to the development of biological substitutes that restore, maintain, or even improve a damaged or diseased tissue (Langer and Vacanti, 1993). Natural, synthetic or semisynthetic materials can be employed to mimic the tissue, being either fully functional or with a capability to grow into the required functionality. Regenerative medicine is considered a broader field that includes tissue engineering as a main topic and is defined as the process of replacing, engineering or regenerating human or animal cells, tissues or organs to restore or establish normal function (Mason and Dunnill, 2008). Selection and design of appropriate materials is one of the main challenges due to the strict number of requirements that should be full accomplished. For example, ideal materials for bone tissue regeneration should mechanically support the damaged area until bone grows in, but in addition should be osteoinductive, osteoconductive, bioresorbable, biocompatible, easy to use, inexpensive and structurally similar to bone (Kwong and Harris, 2008).

Calcium phosphates (CaPs) as well as their composites with both natural and synthetic polymers open a great spectrum of opportunities to render mimicking materials with clearly improved physicochemical, mechanical and biological properties. In addition to their potential use in regenerative medicine, their applications as drug delivery systems have an increasing interest in biomedicine and can in some cases be a complement of its regenerative function. Biodegradable polymers are ideal matrices to form hybrids with CaPs due to have a great design flexibility (e.g., capacity to modify composition and structure). This may allow not only duplicate the characteristics of the extracellular matrix (ECM), but also to accelerate regeneration with respect to natural processes.

Hydroxyapatite (HAp)/polymer composites have a great potential to enhance the healing process of bones, teeth and cartilages (Callister and Rethwisch, 2009). Bones are regenerated, for example, by the action of two differentiated cells lines: osteoblasts, which are mononuclear cells involved in the bone formation process, and osteoclasts, which are multinuclear cells involved in tissue resorption. The natural mineralization process is firstly controlled by cells since nucleation and growth of CaPs take place in their vesicles. Mineral propagation corresponds to the second step that occurs when crystals reach an appropriate dimension. These crystals caused the breakage of the vesicle and become exposed to the collagen and proteins present in the ECM. The mineralization process implies different steps: osteoinduction (i.e., the stimulation of undifferentiated cells to produce osteoblasts and osteocytes), osteoconduction (i.e., the cellular growth into the material, which depends on multiple characteristics like the presence of growth factors and vascularization), and osteointegration (i.e., the contact between the living bone/tissue and the implanted material) (Stevens, 2008). Bone tissue engineering requires to develop complex systems able to provide: Osteogenic cells, a biocompatible scaffold that mimic the ECM, good vascularization to facilitate the efficient transport of both nutrients and wastes, and bioactive signal molecules (e.g. growth factors to promote cell proliferation and morphogens that control tissue generation) (Bharadwaz and Jayasuriya, 2010; Amini *et al.*, 2012).

The present article is organized in several sections that begin with basic topics concerning CaPs and the specific synthesis of HAp. Modification, functionalization and cross-linking of HAp surfaces are then developed. Next steps correspond to the application of HAp as drug delivery systems and non-viral gene carriers. Development of HAp containing hydrogels based on peptide self-assembly and applications in regenerative medicine of scaffolds incorporating HAp are finally explained.

Calcium Phosphates

CaPs have a great interest in different fields (e.g., chemistry, geology, materials science), but probably the most relevant one concerns to biomedical applications due to their wide use as bioceramics, coatings and components in scaffolds for tissue regeneration (Liu and He, 2017; Carino *et al.*, 2018). CaPs can be obtained in different individual phases that differ on their composition, structure, and Ca/P ratio. Degree of substitution (e.g., carbonated substituted compounds), solubility and bioresorbability are also important distinctive features. The most relevant CaPs are brushite (DCPD), monetite (DCPA), octacalcium phosphate (OCP), tetracalcium phosphate (TTCP), tricalcium phosphate (TCP), hydroxyapatite (HAp) and amorphous calcium phosphate (ACP) as indicated in both Table 1 and Fig. 1 (Manjubala *et al.*, 2005). Development of multiphasic systems is currently receiving great attention since none of the above indicated phases gives ideal properties (Dorozhkin, 2016).

OCP is considered the *in vivo* precursor of HAp, which is the thermodynamically stable calcium phosphate form and the main mineral constituent of bone and teeth. Research in bioceramic materials are nowadays mainly focused on TCPs, HAp and biphasic calcium phosphates (BCPs) due to their good biological properties (Kalita *et al.*, 2007). TCPs are characterized by their great degradability and osteoconductivity. Thus, TCPs appear ideal for surgeries involving bone tumors since their dissolution provide a

Table 1 Calcium phosphate phases

Phase	Abbreviation	Compounds	Ca/P ratio
Brushite	DCPD	$\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$	1.0
Monetite	DCPA	CaHPO_4	1.0
Octacalcium Phosphate	OCF	$\text{Ca}_8(\text{PO}_4)_6 \cdot 2.5\text{H}_2\text{O}$	1.33
Whitlockite/Tricalcium Phosphate	TCP	$\text{Ca}_3(\text{PO}_4)_2$	1.5
Calcium Hydroxyapatite	HAp	$\text{Ca}_5(\text{PO}_4)_3\text{OH}$	1.67
Tetracalcium phosphate	TTCP	$\text{Ca}_4(\text{PO}_4)_2\text{O}$	2.0
Amorphous Calcium Phosphate	ACP	–	–

**Fig. 1** Equilibrium phase diagram of different phosphate phases. Based on Manjubala, I., Sastry, T.P., Suresh Kumar, R.V., 2005. Bone in-growth induced by biphasic calcium phosphate ceramic in femoral defect of dogs. *Journal of Biomaterials Applied* 19, 341–360.

favorable Ca and P rich environment for bone formation (Ogose *et al.*, 2005). Low pH conditions created by cells that are in direct contact with CaPs make feasible the dissolution process (Peters and Reif, 2004). As previously indicated, HAp is the main mineral component of bones, teeth, cartilages, and calcified tissues. Usually, it occurs as nonstoichiometric sodium, magnesium, and carbonate containing HAp named biological apatite. Manmade HAp can be used as biocompatible and osteoconductive coatings as well as a nanocomponent of scaffolds based on biodegradable polymers. HAp is a good substrate for the adhesion of proteins, peptides, lipids, bacteria, and cell lines (Aronov *et al.*, 2007), enhance biocompatibility of scaffolds and can provide a reinforcing effect in the form of nanoparticles (Ma, 2004; Turon *et al.*, 2017).

The structure of stoichiometric HAp is defined by a monoclinic unit cell, space group $P2_1/b$, with cell parameters of $a = 0.942$ nm, $b = 2a$, $c = 0.688$ nm and $\gamma = 120^\circ$ (Fig. 2). It is interesting to note that OH^- ions are located in two different columns (Kay *et al.*, 1964). All ions point upward in one column, while in the other one point downward. The monoclinic form is obtained only under very strict thermal conditions. At temperatures higher than 250°C there is a structural transition towards a hexagonal unit cell defined by the $P6_3/m$ space group, and parameters of $a = b = 0.943$ nm, and $c = 0.688$ nm (Elliott, 1994). In this case, the mirror symmetry of the space group implies that OH^- ions are statistically disordered pointing upward and downward of the mirror plane. However, some short-range ordering is postulated (e.g., $\text{OH}^-\text{OH}^-\text{OH}^-\dots\text{HO}^-\text{HO}^-\text{HO}^-$). The reversal of the OH^- being favored by the presence of fluorine or chlorine ions and even by a vacancy. Therefore, the hexagonal form is associated to non-stoichiometric compounds (Mathew and Takagi, 2001).

Calcium deficient hydroxyapatite (CDHA) derives from the substitution of calcium and hydroxide ions with protons. In this way CDHA compounds are defined by the formulae $\text{Ca}_{10-x}(\text{HPO}_4)_x(\text{PO}_4)_{6-x}(\text{OH})_{2-x} \cdot n\text{H}_2\text{O}$ since the interaction of these protons with nearest PO_4^{3-} groups leads to HPO_4^{2-} anions (Dorozhkina and Dorozhkin, 2002). CDHA has higher chemical activity than stoichiometric HAp and plays an important role in bone formation since it induces precipitation of bone-like apatite (Monteiro *et al.*, 2003). Furthermore, this low crystalline CDHA can be slowly resorbed in contrast with the non-resorbable and crystalline HAp. CO_3^{2-} , Mg^{2+} and Sr^{2+} ions can also be easily incorporated in the crystalline structure of HAp by substitution (Bohner, 2000), being logically also enhanced the resorption process.

Synthetic or biological calcium deficient HAp sintered at temperatures higher than 700°C leads to biphasic calcium phosphate (BCP). This is a ceramic material consisting of HAp and TCP that has wide applications for bone grafting. The HAp/TCP ratio depends on the calcium deficiency of the precursor material and specifically decreases when the deficiency increases (Arinzeh *et al.*, 2005).

Synthesis on Hydroxyapatite

HAp particles are usually obtained through chemical precipitation processes which are mainly based on any of the two following reactions:

The precipitation method is very simple but allows a good control over morphology and particle size by modifying the experimental conditions (Pang and Bao, 2003; Saha *et al.*, 2009; Xia *et al.*, 2009; Ye *et al.*, 2010; Huang *et al.*, 2011). Thus, the pH of the initial solutions can be varied and nanorods, nanowires, microsheets, bur-like microspheres or microflower aggregates be obtained as depicted in Fig. 3 (Zhang *et al.*, 2009). In general, basic conditions lead to an isotropic growth due to the presence of OH^- ions onto the crystal surface, whereas anisotropic crystals are favored at low pH due to the limited amount of adsorbed OH^- ions and the consequent limitation for crystallization and growth of HAp. Fig. 4 shows the influence on the HAp crystal morphology caused by changes on stoichiometry, temperature and pH (Kobayashi *et al.*, 2012).

The addition of chelating agents such as citrates and tartrates (López-Macipe *et al.*, 1998; Ma, 2012) is also a suitable way to control the particle characteristics as well as the use of surfactants (e.g., cetyltrimethylammonium bromide, stearic acid or monosaccharides) (Cao *et al.*, 2004) in the precipitation medium or even the use ethanol as solvent instead of water (Layrolle and Lebugle, 1994). Theoretically HAp should be obtained by mixing the solutions containing the stoichiometric Ca/P ratio (i.e., 1.67), but is frequent that phases with other ratios were also stabilized in the formed crystals depending on the synthetic method and the experimental conditions.

Rapid mixing of solutions containing appropriate amounts of calcium and phosphate ions usually renders an amorphous precipitate (ACP), which can be converted into the crystalline HAp by a subsequent hydrothermal treatment (Ren *et al.*, 2013). This process is highly relevant since allows an accurate control of the final crystal morphology. In addition, self-assembly (Saha *et al.*, 2009; Ye *et al.*, 2010), spray drying (Sun *et al.*, 2009), double emulsion (Shum *et al.*, 2009), solvothermal (Ma and Zhu, 2009) and sol-gel (Dou *et al.*, 2012) methods have been applied to get HAp particles.

Surface Treatment of HAp Nanoparticles

HAp surfaces have a great importance for biomedical applications since they are primordial to establish interactions when implanted with surrounding cells, to absorb and deliver peptides, morphogenetic proteins, antibiotics and drugs (Lee *et al.*, 2014). Absorption of proteins depends for example of the surface roughness (Rechendorff *et al.*, 2006) and charge of the growth face. Ions located on the HAp surface (Ca^{2+} or PO_4^{3-}) can interact with the NH_3^+ and COO^- groups of proteins favouring adsorption.

A precipitation process in presence of amino acids may lead to their immobilization and neutral, acid or basic surfaces depending on the nature of the amino acid. Thus, HAp surfaces having acidic amino acids like aspartic acid are ideal to adsorb positively charged proteins (e.g., lysozyme). For the same reason basic amino acids like arginine can adsorb negatively charged proteins (e.g., serum albumin) (Lee *et al.*, 2012). Incorporation of charged small compounds like citric acid have also been demonstrated efficient for enhancing protein adsorption (Lee *et al.*, 2013b). Surfaces having immobilized arginine-glycine-aspartic acid (RGD) peptides and collagen (COL) are especially interesting since favor cell attachment, cell differentiation and bone remodeling.

Fig. 3 SEM images showing different morphologies of HAp crystals obtained at different pH values. (a, b) nanorods at pH 7.0, (c,d) bur-like microspheres at pH 5.0, (g, f) microflowers at pH 4.5, and (e, h) microsheets at pH 4.0. Reproduced with permission from Zhang, C., Yang, J., Quan, Z., *et al.*, 2009. Hydroxyapatite nano- and microcrystals with multiform morphologies: Controllable synthesis and luminescence properties. *Crystal Growth & Design* 9, 2725–2733.

A major problem of HAp employed in biomedical applications is the risk of infection caused by the lack of protection from the immune system. Preventive solutions try to avoid the use of antibiotics by the incorporation of Cu^{2+} and Ag^+ ions that are able to inhibit bacterial growth through different mechanisms (Hu *et al.*, 2007; Holt and Bard, 2005; Kim *et al.*, 2007; Lim *et al.*, 2015). Ions can be incorporated by coprecipitation (CP) and ion exchange (IE) (Holt and Bard, 2005). In the first case, the phosphate precursor solution is slowly added over a solution mixture of the calcium precursor and the bactericidal ion, whereas in the second case HAp is immersed in a solution of the bactericidal ion to facilitate ion exchange. The applied methodology affects ion distribution (i.e., bulk or surface for CP and IE, respectively), the bactericide response (fast for IR) and the cytotoxicity (high for IE).

Fig. 4 Influence of the stoichiometric ratio, pH and temperature on the morphology of HAP crystals developed in simulated body fluid (SBF) solutions. Indices indicate the crystal growth faces. Based on Kobayashi, T., Ono, S., Hirakura, S., Oaki, Y., Imai, H., 2012. Morphological variation of hydroxyapatite grown in aqueous solution based on simulated body fluid. *Crystal Engineering Communications* 14, 1143–1149.

Surface modification of HAP can also lead to exfoliated structures that are basic as reinforcing materials (Zuo *et al.*, 2013) and even as carriers for DNA (Zuo *et al.*, 2011). Treatment of HAP with polysaccharides like chitosan (CS) (Zakaria *et al.*, 2013) and even its glucosamine monomer (Luo *et al.*, 2016) has been proved to favor the exfoliation process.

Synthetic bone material substitutes (e.g., BCP) are usually too brittle for long-term applications (Rao, 1995). An interesting strategy to avoid this problem consists on the grafting of an appropriate polymer on the CaP surface. Furthermore, grafting may lead to the improvement of other specific properties such as osteoconductivity (e.g., BCP grafted with poly(glycidyl methacrylate) (Thangavelu *et al.*, 2016)), control of adhesion and cell differentiation by electric stimulation (e.g., HAP grafted with aniline tetramers (Liu *et al.*, 2013)), enhancement of osteoblast proliferation (e.g., HAP grafted with poly(γ -benzyl-L-glutamate) (Wei *et al.*, 2009)). HAP has also been grafted with polylactide (PLA) to improve compatibilization in a nanocomposite having PLA (Hong *et al.*, 2004) or poly(glycolide-co-lactide) (Tang and Liu, 2014) matrices. COL has also successfully grafted onto hydroxyapatite materials following different strategies (Yang *et al.*, 2016; Bhuiyan *et al.*, 2015) that could even render crosslinked materials.

Cross-Linked Materials Derived From Reactions on HAP Surfaces

Poor mechanical properties of hydrogels may limit their inherent applications to regenerate hard tissues systems. Therefore, it appears highly interesting to improve mechanical properties and even to provide functional properties by establishing physical links between the surface of inorganic HAP particles and selected polymers like COL, CS, alginate (ALG) or cellulose.

These biopolymers can be subsequently cross-linked using an appropriate agent as it is the case of genipin (GNP). A typical example corresponds to the reaction of an antiporosis drug (e.g., alendronate, ALN) on the HAP surface and the subsequent formation of a COL-based hydrogel using GNP as an effective crosslinking agent (Fig. 5) (Ma *et al.*, 2016).

Cross-linking of CS with HAP was also possible by reaction of an azide functionalized CS with HAP nanoparticles incorporating alkyl groups (Pradal *et al.*, 2011). These particles were prepared by the addition of propiolic acid in the typical precipitation medium employed for HAP synthesis (Wei *et al.*, 2014). Dopamine was also employed as a cross-linker agent between HAP and CS, having the derived materials improved mechanical performance and cell adhesion (Prajatelistia *et al.*, 2015).

Incorporation of HAP into a polymer matrix may promote a gelling process due to the release of Ca^{2+} ions that could establish interactions with, for example, the carboxylic groups of different biopolymers. It is interesting to note that inorganic nanoparticles can also provide a clear reinforcing effect of the matrix. Thus, HAP was appropriate to promote the gelation of the anionic pectin polysaccharide giving rise to an injectable system for bone tissue regeneration (Munarin *et al.*, 2015).

Partial release of Ca^{2+} ions from HAP was also fundamental to establish cross-linked hydrogels with ALG and CS (Sukhodub *et al.*, 2016). Hydrogels were formed in the precipitation stage by means also of interactions between hydroxyl, amino and carboxyl groups of the indicated biopolymers.

Three-dimensional nanocomposite structures have been developed by in situ synthesis of HAP in presence of carboxymethyl cellulose through physical cross-links between Ca^{2+} ions and carboxyl groups (Garai and Sinha, 2014). This process mimics bone formation due to the simultaneous occurrence of synthesis and assembling in the organic matrix and lead to materials with high compressive stress, high modulus and applicability as bioactive bone grafting.

Cross-linked systems can also be produced by using synthetic polymers like polycaprolactone diacrylate. In this case, HAP was added before to initiate a thermal cross-linking process that led to porous materials with high modulus and osteoconductivity (Koupaei and Karkhaneh, 2016).

Fig. 5 Synthesis of COL/HAp-ALN hydrogels. Based on Ma, X., He, Z., Han, F., *et al.*, 2016. Preparation of collagen/hydroxyapatite/alendronate hybrid hydrogels as potential scaffolds for bone regeneration. *Colloids and Surfaces B: Biointerfaces* 143, 81–87.

Applications of HAp Based Materials as Drug Delivery Systems

The high adsorption and binding capability of HAp surfaces has been explained in the previous sections and appears a fundamental property to develop drug delivery systems. Furthermore, HAp can be dissolved in acidic environments as the lysosome vesicles of cells and even in the acidic extracellular environment of cancer cells. Therefore, both bulk incorporated compounds during the synthesis procedure and surface adsorbed bioactive molecules can efficiently be released. In the first case, a homogeneous distribution and a slow release can be attained, while in the second case a local, scarcely controllable and fast delivery are characteristic. Obviously, the control on the nanoparticle morphology (e.g., needle- plate-shaped or spherical) are primordial to tailor a specific therapeutic behavior (Roveri and Iafisco, 2010).

Antibiotics and growth factors and typical drugs that improve the performance of materials employed in tissue regeneration since they can prevent infections and promote osteoblast differentiation. A sustained work has been performed to develop systems with a local and controlled delivery of encapsulated bone morphogenetic proteins in order to protect bioactivity and prolong their beneficial effect (Liu *et al.*, 2009). Thus, HAp/COL-ALG bionanocomposites loaded with morphogenetic proteins have been successfully developed as a bone filler (Sotome *et al.*, 2004). In a similar way, fibroblast growth factors have been incorporated in HAp/COL bionanocomposites leading to efficient materials to promote bone and cartilage regeneration (Maehara *et al.*, 2010). The (PDGF)-BB grown factor has also been adsorbed in the HAp surface of polycaprolactone (PCL) /COL/HAp nanocomposites, giving rise to an enhanced stimulation of osteoblast chemotactic migration and therefore favouring the bone healing process (Phipps *et al.*, 2012).

As indicated in the previous section ALN is a bisphosphonate with a great capability to suppress bone resorption. Therefore, HAp nanoparticles carrying this drug are interesting since allow combining the osteoconductive properties of HAp with a well-recognized therapeutic effect against osteoporosis. Highly promising results have been achieved using spherical HAp nanoparticles coated with successive layers of poly(allylamine) and ALG, which makes feasible the ALN conjugation (Hwang *et al.*, 2016).

Incorporation of minocycline, a tetracycline antibiotic, has been evaluated due to additional advantages related to the enhancement of bone formation and the decrease of bone resorption. A slow release, and improvement of cell adhesion, proliferation and differentiation was demonstrated for HAp-gelatin nanocomposites loaded with minocycline (Dou *et al.*, 2011). Doxycycline and dexamethasone have also been incorporated in complex systems based on COL and having HAp rods to prevent infection and increase osseointegration (Song *et al.*, 2013a). Different studies have been focused in the load and release of gentamicin due to the positive effect of this aminoglycoside antibiotic against the osteomyelitis disease (Shi *et al.*, 2010; McNally *et al.*, 2016). ALG/HAp nanocomposites loaded with erythromycin provided an antibiotic effect, showed high osteoconduction and resorbability, and had a potential use as an injectable bone filling material (Ferraz *et al.*, 2007).

CDHA/CS nanocomposites loaded with vitamins have also been developed. Nanocrystals were fundamental as effective bioactive fillers and as regulators of the delivery process (Liu *et al.*, 2006).

Fig. 6 Targeted antitumor drug delivery mechanism (nucleus and mitochondrion) of HAP-HAP nanoparticles loaded with DOX. Based on Xiong, H., Du, S., Ni, J., Zhou, J., Yao, J., 2016. Mitochondria and nuclei dual-targeted heterogeneous hydroxyapatite nanoparticles for enhancing therapeutic efficacy of doxorubicin. *Biomaterials* 94, 70–83.

Ca^{2+} ions of HAP can lead to an antiproliferative cancer cell activity and the stimulation of intracellular apoptotic signals (i.e., the activation of caspase protein digesting enzymes and the release of cytochrome C from mitochondria) (Liu *et al.*, 2003; Tang *et al.*, 2014). Therefore, HAP nanocapsules appear as an ideal encapsulation medium of anticancer drugs taking advantage of their inherent activity. The efficacy of the apoptosis effect of HAP seems to increase when the size of nanoparticles decreased (Yuan *et al.*, 2010; Li *et al.*, 2008), a feature that suggests a correlation with cellular internalization (Cui *et al.*, 2016).

Cancer tissues are characterized by an enhanced permeability and retention (EPR), which can be in some cases considered for selective targeting by nanoparticles. The potential control of size and morphology (e.g., spheres, rods or needle-like crystals), and the easy way to perform surface modifications appear a great advantage of employing HAP as drug carrying nanoparticles for cancer treatment. Thus, particles loaded with positively charged CS can establish good interactions with negatively charged cancer cell membranes (Yang and Hon, 2009). This approximation has been for example employed for the treatment of colon cancer by encapsulating celecoxib in this coated system (Venkatesan *et al.*, 2011).

HAP nanoparticles coated with hydrophilic hyaluronic acid (HA) have also been loaded with anticancer drugs as doxorubicin and revealed a promising potential against tumor cells. In fact, HAP facilitates a targeted cancer therapy due to its affinity with glycoproteins that are overexpressed in tumor cells (Fig. 6) (Xiong *et al.*, 2016).

Chloramphenicol (CAM) is a wide-spectrum antibiotic that can induce mitochondrial-dysfunctions in cancer cells. This property has been considered for developing new platforms for cancer therapy. Thus, CAM has been encapsulated in both HAP and ACP nanoparticles coated with pyrophosphates in order to protect the antibiotic during and/or after its release. The greater therapeutic efficacy was found when amorphous particles and a triphosphate coating were employed (Rivas *et al.*, 2018). CAM distribution in the nanoparticles can be varied depending on the precipitation method (Rivas *et al.*, 2019b). In this way, a preferred distribution on the outer part of the particle could be attained giving rise to a fast bactericide effect.

HAP as a Gene Carrier

Immunotherapy strategies allow to boost the immune system of a patient to kill cancer cells or act against other acquired or inherited diseases. The development of non-viral gene carriers is gaining attention since can transport specific disease-associated antigens (Palena *et al.*, 2006). Therefore, the use for example of more conventional surgery, chemotherapy and radiotherapy alternatives can be avoided for the cancer treatment.

Non-viral gene vectors have advantages derived from a scarce (and even null) immunogenicity, easy sample preparation, low cost, and high flexibility to locate selected transgenes with different sizes (Santos *et al.*, 2011). HAP has most of these advantages

and furthermore can establish good interactions with DNA, being an ideal transfection and protection medium. HAp-DNA complexes can be obtained by different methods such as coprecipitation (Bisht *et al.*, 2005), encapsulation (Sokolova *et al.*, 2006) and coating (Welzel *et al.*, 2004). Fig. 7 shows the preparation of nanoparticles with sizes around 100 nm (i.e., appropriated to be endocytized by cells) by coprecipitation in the aqueous core of micellar entities. Modifications of particles is usually necessary in order to prevent their aggregation (e.g., coating with CS (Lee *et al.*, 2013a)), to increase the loading efficiency (ionic substitution with magnesium or strontium for calcium and carbonate or fluorine for phosphate anions) and even to facilitate the dissolution after endocytosis (Chowdhury *et al.*, 2004; Chowdhury, 2011; Hanifi *et al.*, 2010).

Dynamic simulations demonstrated the capability of HAp to encapsulate the double helix of DNA without causing a significant distortion of its secondary structure (Fig. 8) (Revilla-López *et al.*, 2013). Ionic interactions between calcium ions of HAp and the phosphate groups of DNA were essential to form complexes able to act as nucleating agents. These theoretical considerations were experimentally verified (TEM, UV, XPS and electrophoretic techniques) since DNA was encapsulated in both HAp and ACP forms (Manjubala *et al.*, 2005).

Multiple works have been performed about the use of HAp nanoparticles as gene carrier vectors. Thus, structured HAp was found to be able to protect DNA from DNase digestion/degradation (Zuo *et al.*, 2011), pDNA adsorbed on HAp nanocrystals was efficiently transfected into cancer SGC-7901 cells (Zhu *et al.*, 2004), HAp encapsulating malarial merozoite protein-119 showed promising properties to be employed as antigen carriers for immunopotentialization (Goyal *et al.*, 2009), complexes of HAp with arginine have been successfully employed for the treatment of nasopharyngeal carcinoma cells (Chen *et al.*, 2010b), new therapeutic matrices for bone repair have been developed by incorporating the ephrinB2 gene in HAp nanoparticles embedded in a COL matrix (Tierney *et al.*, 2013).

Peptide/HAp Based Hydrogels for Biomedical Applications

Peptide molecules have a self-assembly ability that has been considered for the development of new hydrogels (Hartgerink *et al.*, 2002; Stupp, 2005). These can mimic the extracellular matrix and have been proved very appropriate for different biomedical applications (e.g., regeneration of hard tissues) (Rivas *et al.*, 2019a). Peptide-based hydrogels show inherent advantages like biocompatibility, capacity to establish physical and reversible cross-links under physiological conditions, and trigger capacity. Furthermore, materials can be designed with a great tunability taking advantage of varying amino acid sequence and peptide length, which influence on the final structure and functionality.

The great potential of such materials is obviously linked to the great variability in the composition and length of peptides, which opens the possibility of a tailored design to suit a specific property. The incorporation of charged amino acids in the peptide sequence promotes the interaction with calcium divalent ions, making it possible to use the derived hydrogels for the nucleation of HAp and even the development of nanocomposites. Promising results have been achieved in recent years concerning the development of hydrogels for the regeneration of hard tissues, mainly bone, teeth, and cartilage, as evidenced in the present review.

Peptides can self-assemble following different mechanisms that lead to typical β -sheet structures: (1) Ionic interactions between complementary peptides having opposite charges (positive and negative charges provided by hydrophilic residues like lysine/arginine or aspartic/glutamic, respectively) (Raspa *et al.*, 2014); (2) RADA sequences characterized by an alternate disposition of hydrophilic and hydrophobic units (e.g., Arg-Ala-Asp-Ala sequence with positive and negative arginine and aspartic hydrophilic residues and alanine as hydrophobic residue) (Hori *et al.*, 2007); (3) L,D-heterochiral peptides (Fuertes *et al.*, 2017); Peptide amphiphiles (Hartgerink *et al.*, 2001), and (4) Peptides with N-protected groups able or establish interactions (Tao *et al.*, 2016).

New bionanocomposites based on peptide self-assembling and HAp nanoparticles are characterized by a hybrid structure having inorganic (HAp) and organic (peptides) components that mimics the ECM. Preferred particles have a high aspect ratio and diameters in the nanoscale range. Self-assembling peptides (SAP) constituted an appropriate environment for the cell growth and were able to enhance both cell adhesion (e.g., bone marrow mesenchymal stem cells (BMSCs)) and osteoblast differentiation (Botchwey *et al.*, 2003; Zhang *et al.*, 2018). These characteristics are meaningful in hard tissue regeneration since one of its major problems concern the limited number of cells that can be loaded in the designed scaffolds (Mankani *et al.*, 2011). SAP/nHAp/CHI scaffolds have been, for example, employed to repair femoral bone defects. Non-acidic SAPs (e.g., the SPG-178 peptide based on arginine, alanine, leucine and aspartic acid) were successfully employed together with human bone morphogenetic protein, being detected a clear enhancement of cell proliferation, osteogenic differentiation, and COL and osteocalcin expression (Tsukamoto *et al.*, 2017).

(LE)₈ and (VEVSVKVS)₂ peptides were able to self-assemble, giving rise to nanofibers that could form hydrogels through ionic cross-linking between the carboxyl groups of glutamic acid and added calcium ions. The system was ideal as bone-filling material and could mineralize both HAp and ACP along nanofibers under neutral and basic pHs (Nonoyama *et al.*, 2012).

The external coating of teeth is constituted by an anisotropic arrangement of HAp crystals that is named enamel (Paine *et al.*, 2001). This arrangement is regulated by amelogenin, a protein that is finally eliminated by the action of proteolytic enzymes (Fukumoto *et al.*, 2004). Large enamel lesions are difficult to be repaired, being nowadays interesting the use of self-assembled scaffolds to control HAp growth and provide a mimetic enamel structure (Elkassas and Arafa, 2017). In this way, the peptide amphiphile having a high content of the epitope RGDS was found suitable to induce growth of HAp according to the native

Fig. 9 (A) Molecular model of a KLD-12 self-assembling peptide based on alternating hydrophobic (leucine, L) and hydrophilic (positively and negatively charged lysine, K, and aspartic acid, D) residues that facilitates self-assembling through intermolecular interactions. (B) A 12-mm chondrocyte-seeded peptide hydrogel plug. (C) Light microscope image of chondrocytes encapsulated in peptide hydrogel. Reproduced with permission from Kisiday, J., Jin, M., Kurz, B., *et al.*, 2002. Self-assembling peptide hydrogel fosters chondrocyte extracellular matrix production and cell division: Implications for cartilage tissue repair. *Proceedings of the National Academy of Sciences of the United States of America* 99, 9996–10001.

enamel structure (Huang *et al.*, 2010). Another interesting example is the Ac-Gln-Gln-Arg-Phe-Glu-Trp-Glu-Phe-Glu-Gln-Gln-NH₂ peptide that is able to self-assemble under the low pH of a caries lesion and act as nucleation agent for HAp (Alkilzy *et al.*, 2018). Self-assembly of Fmoc-Val-cetylamine led to nanofibrous gels with great affinity towards HAp and ability to mimic the ECM of osteoblasts (Romanelli *et al.*, 2015).

The cartilaginous matrix mainly consists of COL and proteoglycans, and is produced and maintained by chondrocyte cells. Osteoarthritis is a typical cartilage disease that leads to the loss of functionality and mechanical properties as consequence of the depletion of glycosaminoglycans (Katta *et al.*, 2008). Regeneration of cartilages is hardly difficult due to their avascular character and the absence of stem cells. Strategies for the repair of cartilages are mainly based on the implantation of mesenchymal stem cells (MSCs). Thus, injectable therapies have been feasible by seeding MSCs into AcN-(KLDL)₃-CNH₂, a self-assembled peptide hydrogel able to support the chondrogenesis of the encapsulated cells (Kisiday *et al.*, 2018). Other interesting approaches consist on the use of: (1) Osteochondral constructs based on the HAp interdigitation with a self-assembled neocartilage constituted by COL and glycosaminoglycan (Brown *et al.*, 2018), (2) SAP hydrogels able to retain chondrocytes and facilitate the achievement of a cartilage ECM (Fig. 9) (Kisiday *et al.*, 2002). SAPs based on tryptophan, phenylalanine and charged amino acids (Barco *et al.*, 2018) are interesting since can be delivered as no-viscous fluids that self-assemble once placed in the damaged tissue.

HAp Based Scaffolds for Tissue Regeneration

Scaffolds appropriate for tissue regeneration should have a porous structure, playing the control of geometry, pore size and pore interconnectivity a fundamental role. Different methodologies have been developed to prepare these porous scaffolds, being probably phase separation and electrospinning the most significant techniques.

Thermally induced phase separation (TIPS) gives rise to polymer lean and rich phases by cooling a homogeneous polymer solution. A porous solid structure is derived from the rich phase after solvent removal. Different morphologies (e.g., open or close pores, membrane or fibrous structures) can be attained depending on the separation conditions (e.g., polymer concentration and molecular weight, cooling path) (He *et al.*, 2009). In addition, water soluble porogens can also been added to the initial solution. PLA/HAp scaffolds have been for example prepared by TIPS to mimic the bone matrix and the nanofeatures of bone (Zhang and Ma, 1999).

Polymer fibers with similar dimension than the fibrils existing in the ECM can be obtained by means of the electrospinning technique (Doshi and Reneker, 1995). This is based on the application of a high voltage to polymer solution drops. A charged jet is formed when the applied electrostatic charge is able to overcome the surface tension of solution drops slowly ejected through a capillary. The polymer jet is subsequently deposited into a grounded collector in the form of accumulated micro/nanofibers. Characteristics of scaffolds can be modified according to solution properties (e.g., solvent, polymer concentration and viscosity), environmental conditions (e.g., temperature and humidity) and processing parameters (e.g., applied voltage, flow rate and tip-collector distance).

Electrospinning has some inherent problems that corresponds to the use of solvents since they may be prejudicial for some natural polymers susceptible of denaturation (e.g., the triple helix structure of COL may be lost giving rise to gelatine

Fig. 10 Incorporation of nanoparticles into electrospun fibers: (a) Surface attachment, (b) Partial encapsulation and (c) Complete encapsulation. Based on Tong, H.W., Wang, M., Li, Z.Y., Lu, W.W., 2010. Electrospinning, characterization and in vitro biological evaluation of nano-composite fibers containing carbonated hydroxyapatite nanoparticles. *Biomedical Materials* 5, 054111.

(Zeugolis *et al.*, 2008)), and even they can be retained in the electrospun fiber causing some cytotoxicity. In addition, homogenization of the initial solution may be difficult due to its usual high viscosity.

HAp particles can be easily incorporated in the electrospun fibers by dispersing them in the initial polymer solution (i.e., before processing). Depending on the ratio between the dimension of particles and the diameter of fibers, different distributions can be attained. Surface attachment, partial encapsulation and complete encapsulation are derived when the diameter is lower, similar or greater than the particle size (Fig. 10).

The complete encapsulation should lead to materials with higher mechanical performance, while surface attachment appears ideal to enhance the bioactivity (Tong *et al.*, 2010). Usually, the incorporation of HAp particles reduces the homogeneity and regularity of the electrospun fiber and increase the thickness. The optimization of processing parameters may improve the homogeneity and even diminish the formation of clumps.

Encapsulation of HAp inside fibers may decrease the expected bioactivity provided by the isolated nanoparticles (He *et al.*, 2014), the effect being more significant as the porosity of the scaffold decreases. Mineralization of the scaffold surface (e.g., by a subsequent electrodeposition process) is an interesting solution to keep biological activity.

Scaffolds incorporating HAp for tissue engineering applications are based on natural, modified natural and synthetic polymers. In the first group, COL/gelatin, silk fibroin (SF), ALG and CS are the most relevant. Cellulose acetate is a clear example of the second group, while PLA, PLGA, PCL, poly(hydroxybutyrate) (P3HB), polyvinyl alcohol (PVA) and polyethylene glycol (PEG) are the most employed polymers of the third group. Obviously, mixtures of polymers belonging to different groups have also been employed. Natural polymers seems better than synthetic ones in terms of biocompatibility, degradation rate and lower toxicity of degradation products (e.g., it can be avoided the typical release of acid compounds in the surrounding tissue from PLGA and PLGA polyester matrices), but synthetic polymers offer great possibilities to get enhanced properties through the control of composition and even of the surface topography.

ALG is probably the most applied natural polymer for regeneration of bones, cartilages and even skin due to a similar chemical structure to glycosaminoglycan, which is a major component of the ECM. Carboxylic groups of ALG can form ionic interactions with calcium cations (Zheng, 1997), being these linkage sites able to nucleate and facilitate the growth of HAp crystals in electrospun ALG fibers impregnated with PO_4^{3-} ions (Fig. 11). Resulting scaffolds showed low agglomeration of HAp nanoparticles and high attachment of osteoblasts (Chae *et al.*, 2013).

CS has also a great application due to a skeleton highly similar with glycosaminoglycans and the presence of hydroxyl and amine groups that makes feasible and easy chemical modification. Probably, CS/HAp scaffolds have mostly been prepared by the freeze-drying technique, being demonstrated the reinforcing effect of HAp nanoparticles (e.g. incorporation of 20 wt% of HAp increased the modulus from 3.0 to 4.4 GPa) (Nazeer *et al.*, 2017; Pighinelli and Kucharska, 2013).

COL is the main organic component of the ECM of hard tissues and logically displays good biocompatibility and facilitates cell adhesion and proliferation. Nevertheless, scaffolds based only in COL have a limited interest for bone tissue regeneration due to a very fast degradability, poor mechanical properties and high swelling ratio. Therefore, scaffolds with HAp are receiving increasing attention (Zhou *et al.*, 2016). COL/HAp scaffolds have been revealed highly interesting for the treatment of periodontitis bone imperfections (Liu *et al.*, 2016). The high regeneration capability was demonstrated through both good deposition of new bone structures and vascularization at the imperfection sites, which could be caused by an appropriate interaction between organic and inorganic phases. Porous COL scaffolds incorporating BCP nanoparticles and dexamethasone (DEX) have been prepared by the porogen leaching method (Chen *et al.*, 2018). Materials showed a high osteogenic differentiation of MSCs, which was attributed to the constant release of calcium, phosphate and DEX ions, high biocompatibility and angiogenesis effect.

Electrospun cellulose/HAp nanofibers have been found appropriate to prepare new scaffolds for bone tissue regeneration (Ao *et al.*, 2017), being the size distribution of nanofibers similar to the natural ECM fibers of natural bone. Mechanical properties of the derived scaffolds could reach modulus of elasticity and tensile strength values around 3 and 70 GPa, respectively.

The hydrophobic nature of some synthetic polymers (e.g., PLA, PLGA, PHB and PCL) favors the aggregation of the inorganic HAp particles and enhances the indicated irregular morphology of the electrospun fibers with a high presence of beads. To

Fig. 11 (a) Scheme showing the structure of the “egg box” model of calcium ALG. (b) Calcium ALG incorporating precursor ions for HAp nucleation. (c) mineralized “egg-box” structure with HAp. (d) Scheme showing the cross-linked/in situ synthesized HAp/ALG nanocomposite fibrous scaffold. Based on Chae, T., Yang, H., Leung, V., Ko, F., Troczynski, T., 2013. Novel biomimetic hydroxyapatite/alginate nanocomposite fibrous scaffolds for bone tissue regeneration. *Journal of Materials Science: Materials in Medicine* 24, 1885–1894.

minimize this effect, surfactant molecules can be added to stabilize the HAp/polymer interphase (Kim *et al.*, 2006). Compatibility between the selected polymer and HAp is an additional problem that has in some cases solved by grafting appropriate molecules on the surface of HAp particles. For example, ring opening polymerization of lactide has been performed in the presence of HAp, PLA oligomers were successively grafted to particles having hydroxyl functionality (Song *et al.*, 2013b). HAp can establish good interactions with hydrophilic polymers like PEG so it is a good candidate for developing new scaffolds. Unfortunately, PEG has severe limitations since it is not degradable and furthermore its processing into electrospun nanofibers is difficult. The use of block copolymers (e.g., polylactide-polyethylene glycol-polylactide, PELA) has been undertaken with promising results concerning enhancement of osteochondral cell growth and osteogenic cell expression (Weiner and Wagner, 1998). PEG is also an interesting blending component since its high hydrophilicity facilitates water access in the polymeric matrix and enhanced the degradation of other components like gelatin (Zhou *et al.*, 2016) or SF (Qui *et al.*, 2019). The case of SF is relevant since HAp facilitates the osteogenic differentiation of MSCs and improves mechanical properties, but delays the degradation of SF. Therefore, the blending with PEG can effectively produce a counterbalance effect.

Electrospun PLA scaffolds have also been grafted on their surface with CS through its amine functional groups. HAp can subsequently be deposited on the membrane surface after immersion in simulated body fluid (SBF) (Thien *et al.*, 2013) in a similar way as performed with CS nanofibers (Chen *et al.*, 2013a). In both cases, cell viability was increased after a HAp growth that was facilitated by hydroxyl and amine groups of CS. The mineralization process was effective in a maximum incubation period of six days. In the case, of the PLA/CS scaffold the degradation rate was clearly enhanced with respect to that obtained from pure and hydrophobic PLA.

Poly(vinyl alcohol) (PVA) is another hydrophilic polymer that has interests as a scaffold component. PVA is one of the very few vinyl polymers that is susceptible to degradation under both aerobic and anaerobic conditions (Halima, 2016). Furthermore PVA has good mechanical properties, has an anabolic effect on bone formation, and can be cross-linked through its multiple hydroxyl groups (Sailaja *et al.*, 2009). Electrospun fibers constituted by COL, PVA and HAp have been reported, showing the derived scaffolds good adhesion and proliferation of bone cells (Song *et al.*, 2012). PVA electrospun fibers have also been mineralized by incubation in solutions containing calcium and phosphate ions. Porous scaffolds for tissue engineering applications were derived (Chang *et al.*, 2013). Electrospun coaxial nanofibers having PLA (shell) and PVA (core) have also been prepared (Alharbi *et al.*, 2018). Scaffolds showed appropriate biocompatibility, enhanced mechanical properties (i.e., ductility increased from 40% for pure PLA nanofibers to 110%) and high hydrophilicity (i.e., the water contact angle was so low as 25°). Basically, the water molecules could pass through the PLA channels/porous and be absorbed in the hydrophilic PVA core.

Incorporation of HAp particles on polyester matrices is beneficial since could slow down their degradation rate in HAp-dependent manner but more interestingly basic HAp can neutralize the acidic byproducts generated during the polymer degradation process causing a lower inflammatory response after the scaffold implantation.

PCL is an interesting synthetic polymer due to its appropriate biocompatibility, and high toughness and mechanical strength, (Shor *et al.*, 2007). Probably, the slow degradation rate of PCL and its high hydrophobicity may hamper potential applications in tissue engineering (Fabbri *et al.*, 2010). Nevertheless, PCL scaffolds containing HAp showed promising biological characteristics. Thus, the *in vivo* bone generation efficiency of electrospun PCL/HAp scaffolds has been demonstrated (Fu *et al.*, 2012). Surface modification of PCL scaffolds has been performed by electrospraying HAp. Specifically, adhesion, proliferation and differentiation of MSCs was demonstrated, being this treatment available for other polymeric matrices (Venugopal *et al.*, 2013). Complex bioinspired honeycomb systems based on electrospun PCL fibers and electrosprayed HAp particles were obtained using a micropatterned collector. These scaffolds showed a great potential in maxillofacial surgery (Naudot *et al.*, 2020).

Electrospinning has also been combined with electrodeposition techniques in order to produce mineralized scaffolds. Aqueous electrolytes containing, for example, $\text{Ca}(\text{NO}_3)_2$ and $\text{NH}_4\text{H}_2\text{PO}_4$ can be employed leading to formation of apatite in the cathode electrode after applying a current. A platinum coil bent is usually employed to provide a conductive cage to locate the organic scaffold (Naldoni *et al.*, 2011). Electrodeposition led to the formation of HAp flat crystals on the outer surface of the scaffold, a morphology that contrast with the core-shell constructs usually obtained by a conventional SBF incubation processes (He *et al.*, 2014) (Fig. 12).

3D printing technologies are currently been developed for the preparation of scaffolds with complex geometries, being also appropriated to reproduce bone defect shapes (Trombetta *et al.*, 2017) (Fig. 13).

Fig. 14 Scheme showing the modeling of PLA scaffolds incorporating carbonated hydroxyapatite (cHA) by the FDM technology and the subsequent loading of biochemical signals. Reproduced with permission from Oladapo, B.I., Ismail, S.O., Zahedi, M., Khan, A., Usman, H., 2020. 3D printing and morphological characterization of polymeric composite scaffolds. *Engineering Structures* 216, 110752.

High accuracy 3D structures can be prepared by stereolithography if there are available appropriated liquid resins suitable of solidify by postcuring with a light source. HAp can be incorporated in the resins in order to enhance bioactivity. Thus, photo crosslinkable poly(D,L-lactide) having diacrylate groups has been successfully employed, being the stiffness of the cured resin dependent on the amount of incorporated HAp (Ronca *et al.*, 2013).

Different examples can be mentioned about the preparation of 3D biopolymer hybrid scaffolds by means of fusion and deposition modeling (FDM), using a continuous thermoplastic polymer filament. This technology is, economic, fast and suitable for manufacturing complex systems. Scaffolds constituted by PLA and carbonated hydroxyapatite (cHA) were found suitable for the treatment of cranial defects (Balogun and Oladapo, 2016) and in general for bone tissue regeneration (Oladapo *et al.*, 2020) (Fig. 14). The amount of loaded HAp could be successfully increased up to 50 wt% (Corcione *et al.*, 2019). Blends of PLA/CS incorporating HAp have also been processed by FDM (Ranjan *et al.*, 2019).

Selective laser sintering (SLS) has also been applied to fabricate BCP-based scaffolds for tissue engineering applications (Zeng *et al.*, 2020). Materials were biocompatible, favored cell adhesion, had osteogenic and healing potential.

Conclusions

Hydroxyapatite is a calcium phosphate with a high chemical similarity to bone, teeth and cartilages. Excellent biocompatibility, bioactivity and osteoconductive properties make HAp an essential material for hard tissue repair and replacement. Furthermore, biomedical applications can be extended to coatings, hydrogels, scaffolds, and carriers for drug, growth factor and gene delivery.

The interest on HAp nanoparticles is continuously growing due to their absorption and encapsulation capabilities. Furthermore, HAp nanoparticles can act as a "Trojan Horse" since they can be easily endocytized by cells where subsequently can deliver drugs or genes. In addition, HAp is a polyvalent substrate that can incorporate both ions and molecules giving rise to nanoparticles with antimicrobial activity.

The low strength of HAp is a limitation that precludes the manufacturing of implants constituted integrally by this inorganic material. Therefore, scaffolds employed in tissue engineering correspond to nanocomposites where natural (e.g., gelatin, ALG and CS) and synthetic (e.g., PLA, PLGA and PCL) polymers constituted the biodegradable matrix. Great efforts have recently been focused to develop three dimensional biomimetic materials with tuneable characteristics regarding porosity (e.g., pore size and interconnectivity), degradation rate, mechanical properties, bioactivity and resorption rate. Despite the enormous advances on tissue engineering there are still clear technological limitations for reproducing complex tissues. Conventional processes (e.g., electrospinning and phase separation) had reduced reproducibility and low cell deposition accuracy. 3D technologies showed a great potential but are still far from ideal to recreate complex systems. Capacity of new biocomposites to fulfill their promising expectations after implantation in large bone defects under constant and high stress should be verified.

New strategies are being opened thanks to the great potential of nanotechnology. Thus, surface nanotopographic modifications for the regulation of cell differentiation or advances on peptide self-assembling to render physical cross-linkable gels merit attention. In any case, new insights in the comprehension of the interactions between cells and biomaterials appear fundamental to develop suitable materials for clinical treatment.

Introduction

Conventional Drug therapy for any illness follows the principle of attaining effective and desired plasma concentration of the therapeutic drug. Plasma concentration is reached by varying the frequency and dosage of the therapeutic molecules after the evaluation of their half-life. This approach heavily counts on the extensive use of drug molecules coated and compressed to manufacture capsules or tablets. The conventional form of drug therapy faces several limitations like rapid drug clearance, low bioavailability, low patient compliance, limited half-life, high toxicity and absence of selectivity. Developing a novel drug particle to surmount these barriers is time-consuming and pricey (Tiwari *et al.*, 2012). So, to solve the issues of conventional drugs, the investigators started exploring ways to ameliorate the efficiency and safety of generic medicines. Drug Delivery Systems (DDS) were thus worked upon for safer use of available drugs, to attain a better scope of selectivity, less toxicity and extended half-life. The introduction of DDS as a biologically suited structure for the targeted transportation of therapeutic factors got immense recognition lately. DDS acts as an interface connecting the patient and the active drug molecules. The drug delivery process follows the sequence of treatment with the therapeutic product followed by the discharge of the functional components from the product, and then the distribution of the functional components to the target site. It is advantageous, owing to its property of selectivity with a controlled rate of release (Patra *et al.*, 2018; Liu *et al.*, 2016a). Drug delivery applications are now being practiced for numerous diseases, including its extensive application for cancer research. Cancer is the second most cause of global mortality following cardiovascular conditions. It is an unrestrained progression of cells followed by deterioration of tissues or organs. There are quite a few types of cancers, varying on the organ of their origin. Chemotherapy, radiotherapy, resection and immunotherapy are practiced for the cancer treatment. The drawback associated with persistent chemotherapy is the advancement of drug resistance by the tumor cells. It has been suggested that combinational therapy practices can avoid drug resistance and can be more efficient in cancer treatment. Technical advancements in the progression of DDS have hugely transformed the conventional practices of medication. This advancement would never have been possible without the uncompromising study in the area of biomaterials across the world (He *et al.*, 2020; Senapati *et al.*, 2018). It would be pertinent to mention a historical sketch of the biomaterial applications. Though the derivation of the word 'Biomaterial' cannot be traced very precisely, yet the developments with time can be outlined. The history of biomaterial applications can be drawn back to more than 2000 years ago where gold was generally utilized for dental ailments by Chinese and Romans. In the early twentieth century, the developments in biomaterials got accelerated due to the dawn of synthetic plastics. Much of the progress was seen during World War II. The Society of Biomaterials was formed in 1975 after a chain of symposia in the 1960s and 1970s (Huebsch and Mooney, 2009). It will be no hype that current fields like Drug delivery, Biosensors, Tissue Engineering and Theronastics owe a lot to biomaterials. Roughly, a biomaterial can be defined as a material that is non-toxic, biocompatible and does not elicit any unpropitious immune response when it encounters the living tissues. It has been said that the concept of biocompatibility becomes the central dogma of the biomaterials. Biocompatibility is the "ability of a material to perform with an appropriate host response in a specific application" as defined in David Williams Dictionary of Biomaterials. Biocompatibility is an intricate process, and it depends on numerous factors. It is a safety evaluation, and it labels the identification of suitable host response against the contact with biomaterial-based device or system (Ghasemi-Mobarakeh *et al.*, 2019). It relates the assets of biomaterial with the specific area of application. It accesses the time duration for the start of an immune rejection. The idea of biomaterial devices gets beaten if it begins an unfavorable immune response, which will eventually commence to the refusal of the device by the body. Much of the scientific research on biomaterial-based systems endeavor on improvement in the properties of materials to minimize the improper response in-vivo (Anderson, 2019).

Biomaterials are broadly classified as Natural, Synthetic and Semi-synthetic materials. A considerable amount of development in the biomaterial evolution involves polymers as significant players. Natural polymers obtained from bacteria, weeds, plants, and other living organisms are biocompatible in nature, less toxic, and biodegradable. It is said that the inadequate mechanical strength of natural polymers limits their widespread applications. These natural polymers are nowadays chemically modified to expand the mechanical durability and for the integration of the desired property. Extra functionalities are being affixed to the original polymer chains to meet the clinical needs, high drug loading capacity and controlled release (Mohan *et al.*, 2016). Such alterations require meticulous monitoring for maintaining the balance between the changes of the properties with no increase in toxicity. Another approach involves the crosslinking of two different polymers for accomplishing desired assets. Crosslinkers interconnect the molecules between the different polymeric chains. This practice was suggested as a result of inefficient attributes of individual polymers. Although the crosslinking might increase the weight of the polymer blends and provide them with enhanced stability, it might affect the degradation quality with a tangible addition in toxicity (Mogoşanu *et al.*, 2016). Composites are the systems engineered with two or more discontinuous phases having a significant difference in chemical and physical properties. The compositional entities are usually immiscible and separate at the macroscopic level. The constituents of a

composite structure are roughly categorized into two units known as continuous phase (Matrix) and discontinuous phase (dispersed phase, fillers, reinforcing agent) (Mogoşanu *et al.*, 2016). The continuous phase occupies the notable volume of the composite material providing a favorable environment for other dispersed phases to maintain their integrity and position. The matrix provides the fundamental structure for the other constituents. Composites can be either homogenous (equal spreading of the dispersed phase throughout the matrix) or heterogeneous (with unequal distribution of dispersed phase) (Matthews and Rawlings, 1999; Wang, 2003).

Biocomposites are the composite systems built up of biodegradable polymers for extensive biological applications. The fundamental guiding force after the growth of biocomposites is to accomplish the required strength, desired transport mechanism, flexible erodible properties, and biocompatibility. Natural polymers, as well as synthetic polymers, are engaged in the fabrication of biocomposites widely explored for their applicability in tissue engineering and drug delivery. Another benefit of biocomposites is the synergism of its constituents to produce unique properties in the composite. The characteristics of biocomposites can be altered by controlling the features like the number of dispersed phases, dispersion phase, and the quantity of each dispersed phase and varied processing methods. Chiefly the higher reinforcement presents with high strength to the composite. Strength depends a lot on the grip between the phases governing the tensile strength. Different polymeric chains interact in the form of various bonds ranging from weak hydrogen bonds and van der Waal forces to high strength covalent bonds (Gurunathan *et al.*, 2015). The hydrophilic and the hydrophobic chain arrangements govern the steadiness of the composite structure. Bionanocomposites are the biocompatible and biodegradable nanostructured composites. They earned much value in the last decade with the advancements in the field of drug delivery (Mokhtarzadeh *et al.*, 2016). The present article focuses on the biocomposite polymers for drug delivery in cancer. It highlights their physicochemical properties, classifications of the polymers, development methods and wide applications of biocomposite polymer matrix based drug delivery various cancer types.

Classification of Biopolymers Exploited in Matrix Development

Biopolymers used for composite matrices to formulate DDS are broadly classified as Natural and Synthetic polymers.

Natural Polymers

Natural polymers are acquired from a broad spectrum of plants, animals, and microbes. They are formed during the organism's life as an elemental part and are biodegradable. The sophisticated metabolic machinery of cells carries out the chain reactions required for the maturity of a polymer from the monomer substrates. These polymers can be linear or branched, comprising hundreds to thousands of basic monomeric units. Natural polymers can have their fundamental structures in the form of carbohydrates, proteins and lichens. Microbes all over nature are found occurring inside the biofilms, which are exopolysaccharide chains made up of monosaccharides or disaccharide monomers (Rehm, 2010; Kenar *et al.*, 2019). The microbial population is the source of a large group of endopolymers and exopolymers. Terrestrial as well as aquatic flora and fauna are the source of a comprehensive range of carbohydrate and proteinaceous polymers. Owing to the natural origin of such polymers, seasons and species of an organism determine their attributes. Natural polymers are the primary metabolic components of such organisms, and they demand to be extracted for their wide applications. These polymers have many advantages, including their low prices, broad availability, non-toxic nature and biodegradability. However, they are poor at mechanical or tensile strengths and thermal properties (Verma *et al.*, 2019; Jain and Jain, 2015; Jain *et al.*, 2013; Tiwari *et al.*, 2019; Subudhi *et al.*, 2015; Bishnoi *et al.*, 2020; Prajapati *et al.*, 2019a; Kumari *et al.*, 2018; Jain *et al.*, 2018a,b; Verma *et al.*, 2018). **Fig. 1** depicts the origin-based classification of polymers.

Synthetic Polymers

After Natural polymers, there was a resurgence in the exploitation of synthetic polymers for biological applications. To date, they have been explored for, drug delivery, controlled release capsules, bio-packaging, tissue regeneration and implants. The most commonly studied polymers include PEG, PLA, PLGA, PMMA, and PCL (Bastioli, 2020; Jain *et al.*, 2020; Kumari *et al.*, 2018, 2016). A broad spectrum of investigations across the globe has been reported for these synthetic polymers. They provide better tensile strength and are often looked upon for the improvement of mechanical and thermal strength. From drug delivery point of view, PEG is the most exploited polymer ranging from low molecular weight chains to high molecular weight chains and from pure PEG chains to its derivatives (Saraf *et al.*, 2020a; Jain *et al.*, 2019a; Jain and Jain, 2018, 2017, 2016b; Saraf *et al.*, 2016; Jain and Jain, 2016a; Jain and Sanjay, 2016; Jain and Jain, 2016c). **Table 1** summarizes exploited polymers for the development of the biopolymer matrix.

Desired Physicochemical Properties of Biopolymers for Composite Development

Biopolymers are exploited for their unique properties while the development of composite matrices. Each composite is formulated to achieve desired characteristics by the perfect blend of unique attributes possessed by its constituting polymers (Masuelli and Renard, 2017). These polymers have several characters elaborated as follows.

Fig. 1 Origin-based classification of polymers.

Biocompatibility

The biopolymer composites should be biocompatible and it is determined by its applicability. The factors which influence the biocompatibility of biopolymer-based systems include material contact with the surroundings, duration of the interaction, functional characteristics, surface, and architectural compatibility. Alginate gained a lot of weight by the virtue of its attributes and extensive application possibilities in biomedical fields. Biocompatibility studies have been reported for alginate and alginate-blends. They present an array of in-vitro assays for the estimation of the biocompatibility related to alginate formulations (Spasojevic *et al.*, 2014; Dhalendra *et al.*, 2020). Oral administration of alginate is believed to be safe by the FDA. Spasojevic *et al.* reported the immune responses due to the paucity of proper purification of alginate during extraction (Spasojevic *et al.*, 2014). Similarly, Albumin is a readily found plasma protein in animals that has been extensively accepted for the development of DDS. Albumin and albumin-based formulations have been examined for their toxic responses. Most of the investigations point towards the biocompatible nature of the albumin formulations. Abraxane was the first Albumin-Paclitaxel system which got accepted by the FDA for the cancer chemotherapy. Similar to alginate, chitosan is a much desired polymer, and it is one of the most used polymers as well. It is generally utilized for the matrix formulations. The majority of the findings assume it to be non-toxic established on its FDA approval for wound dressings. This approach is erroneous if we talk about nanoparticles, microparticles or other regenerative applications. Chitosan is a positively charged polymer which interacts with the negatively charged membranes of our cells (Rodrigues *et al.*, 2012). A proper nexus of protocols should be followed while assessing the biocompatibility of chitosan. Other polymers like gellan gum, carrageenan, dextran, hyaluronic acid agarose, PEG and PLGA are being looked upon for a number of applications. The toxicity studies have been performed for their in-vitro and in-vivo usage (Lim *et al.*, 2010; Cadée *et al.*, 2000; Liu *et al.*, 2017; Da Silva *et al.*, 2018; Cai *et al.*, 2018).

Mucoadhesiveness

Mucoadhesion can be described as the attractive force between the biological material and the mucus layer. There are numerous theories to elucidate the adhesive mechanisms. This adhesion is mostly hydrophilic interactions and hydrogen bonding. It is of absolute value to appreciate these hydrophilic bonding while formulating efficient films for application. Oro-mucosal DDSs is advantageous over the conventional oral drug delivery as it can easily escape the acidic atmosphere of the stomach, intestinal enzymes and the first-pass metabolism. Though it is advantageous over conventional oral drug delivery, there are challenges in their efficient development and functioning (Brandl and Bauer-Brandl, 2019). The lag in the initiation of a proper adhesion between the mucosal layer and the delivery system paves limitations. Hydroxypropyl methylcellulose and sodium alginate have been broadly explored for their mucoadhesive properties. The usage of biopolymer matrices has made a considerable contribution to the sublingual delivery as well (Ammar *et al.*, 2017). Synthetic polymers and clay provide the mechanical and thermal properties to the biocomposite matrices. Trastullo *et al.* reported higher drug penetration from the polymer blends of HPMC gelatine, chitosan and sodium hyaluronate. Another challenging field is of ophthalmic drug delivery. The liquid drops used for correcting eye ailments are not absorbed well, and there is a demand for more efficient ways (Liu *et al.*, 2016b). Bionanocomposite nanoparticles are now being developed for sustained ophthalmic delivery of drugs.

Table 1 Exploited polymers for the development of the biopolymer matrix

<i>Natural Polymers</i>				
<i>Polymer</i>	<i>Source</i>	<i>Composition</i>	<i>Application</i>	<i>Reference</i>
Hyaluronic acid	All vertebrates	D-glucuronic acid and <i>N</i> -acetyl-D-glucosamine	Spinal cord injury, bone and cartilage repair, drug delivery, cancer-targeting moiety	(Prajapati <i>et al.</i> , 2020b, Prajapati <i>et al.</i> , 2019b, Pulakkat <i>et al.</i> , 2016)
Chitosan	Animal exoskeletons and shells	D-glucosamine and <i>N</i> -acetyl-D-glucosamine	Wound healing, orthopedics, cardiac repair, neural tissue engineering, cornea repair, drug and gene delivery	(Jain and Jain, 2013, Wang <i>et al.</i> , 2020)
Carrageenan	<i>Chondrus crispus</i> seaweed	Galactose and Anhydrogalactose	Skeletal tissues regeneration, cell delivery system	(Rode <i>et al.</i> , 2018)
Agarose	Red weed	D-galactose and 3,6-anhydro-L-galactopyranose	tissues regeneration, cartilage substitutes nerve regeneration, cancer drug delivery	(Zarrintaj <i>et al.</i> , 2018)
Gelatine	Animal skin and bones	Ala-Gly-Pro-Arg-Gly-Glu – 4Hyp-Gly-Pro	Wound healing, drug delivery, soft tissue engineering, cell delivery, and in vitro stem cell maintenance	(Yang <i>et al.</i> , 2018)
Fibronectin	Produced in animal liver	Polypeptide chains; Protein dimer	Wound healing, stem cell differentiation, cardiac repair, bone regeneration	(Casanova <i>et al.</i> , 2020)
Albumin	Present in animals	60–70 kDa protein	Drug carrier, bioprinting, tissue regeneration, cancer drug delivery	(Zhang <i>et al.</i> , 2020a)
Starch	Derived from plants	Homo-glucose polymer	Binding agent, drug delivery	(Torres and Troncoso, 2020)
Alginate	Brown algae	(1–4)-linked β -D-mannuronate (M) and its α -L-guluronate	Bioprinting, Drug delivery, stem cell differentiation, cancer drug delivery	(Jain and Bar-Shalom, 2014, Soltan <i>et al.</i> , 2019, Jain <i>et al.</i> , 2018a)
<i>Synthetic Polymers</i>				
PLA	Polyester of two monomers: Lactic acid and cyclic di-ester lactide	3D-printing, bioprinting, biodegradable medical devices, tissue engineering, drug delivery	(Gregor <i>et al.</i> , 2017)	
PLGA	Poly(lactic-co-glycolic acid)	Biomedical devices, drug carriers, 3D-bioprinting, Hydrogels	(Zhang <i>et al.</i> , 2017, Zhang <i>et al.</i> , 2020b)	
PCL	Poly caprolactone Ring opening polymerization of ϵ -caprolactone	Implants, medical devices, drug delivery, tissue engineering	(Arunraj <i>et al.</i> , 2013)	
PEG	Poly ethylene oxide - H – (O – CH ₂ – CH ₂) _n – OH	Spinal cord injury, drug delivery, Tissue engineering, laxatives, cosmetics	(Kondiah <i>et al.</i> , 2020)	
PAA	Poly Acrylic Acid Homo-polymers of acrylic acid	Hydrogels, orthopedic implants, tissue engineering, cosmetics	(Chuah <i>et al.</i> , 2018)	
PMMA	Poly(methyl-Methacrylic acid)	Bone implants, lenses, bone cement, drug delivery	(Chen <i>et al.</i> , 2018)	

Gel-Forming Ability

Natural biopolymers usually possess hydrophilic character and gel-forming attributes. In water, they form a cross-linked mesh and can be utilized to embed the active molecules inside them. These gels are often referred to as hydrogel. A hydrogel can change its structure accompanied by the change in volume upon getting an appropriate stimulus like temperature or pH change. They are being explored for their tissue regeneration property in ailments such as spinal cord regeneration, rheumatoid arthritis, soft tissue ailments etc. (Ahmed, 2015; Li and Mooney, 2016). These hydrogels hold the feature to provide an appropriate framework for the cells and tissues to grow. Alginate and chitosan are the polymers of choice for the hydrogel formulations. Other polymers such as cellulose, gelatin, hyaluronic acid, collagen and PEG are also used for hydrogel developments for several applications. Injectable hydrogels are now being worked upon for better patient compliance and to ease the complication of targeted delivery of drugs (Narayanaswamy and Torchilin, 2019).

Principal Targeting Approaches for Drug Delivery to Cancer

Passive Targeting

In this, the macromolecules including nanocarriers consolidate especially in the cancerous tissues due to a mechanism of enhanced permeability and retention (EPR). In some conditions, the endothelium blood vessels become leakier than in the normal condition. In the case of hypoxia, the speedily growing tumor admits newer vessels or engulfs pre-existing vessels. Basically, the penetration of

Fig. 2 Principal targeting approaches of drug delivery to cancer (A) Passive targeting and (B) Active targeting.

particles/macromolecule or carrier system depends on the size, impaired lymphatic drainage and leaky vasculature and. The carrier system or macromolecules enters through the capillaries of leaky tumor or by passive diffusion mechanism. The low molecular weight compounds enter by the diffusion (**Fig. 2(A)**). Convection via the tumor interstitium is deprived owing to interstitial hypertension, excluding diffusion as the leading discipline of drug transport ([Bertrand et al., 2014](#)). The EPR phenomenon plays a key role while designing the drug carrier system for cancer-targeting. Furthermore, for approximately all rapidly developing solid tumors the EPR effect is appropriate. Literally, it can be seen in all types of cancer except the hypovascular tumors (prostate or pancreatic cancer) ([Maeda et al., 2001, 2009](#); [Shukla et al., 2019](#); [Panda et al., 2019](#)). Some characteristics are especially important for these purposes are (1) the macromolecule or carrier should be anionic or neutral to circumvent the renal elimination; (2) nanocarriers should be stealthy from reticuloendothelial system to avoid their relapse via opsonization subsequent to phagocytosis. The size should be near to 10–100 nm to avert them from the evasion of kidney filtration. The size should exceed 10 nm and it must be smaller than 100 nm to prevent their stockpiling in the liver ([Gullotti and Yeo, 2009](#); [Nie, 2010](#)). Though, the EPR effect offers somewhat modest tumor exclusivity with 20%–30% in delivery rises than normal organs. The influence of EPR highly depends on the tumor biology and in particular: (1) the extent of perivascular tumor growth and the density of the stromal response, (2) the extent of lymphangiogenesis and angiogenesis, (3) intratumor pressure ([Arap et al., 1998](#)). It is likely to modify the EPR effect mechanically or chemically to attain vascular normalization to highly accretion of nanosystems. Some examples of chemical enhancers of EPR are prostaglandins, peroxynitrite, nitric oxide, bradykinin (kinin), vascular permeability factor /vascular endothelial growth factor and other cytokines, the use of such enhancers momentarily extend tumor perfusion ([Attia et al., 2019](#)).

Active Targeting

The active targeting is imperative to deliver the drugs, theranostics, or gene to the desired site averts their entry to normal tissues and so boosts the therapeutic competence and limits the side effects. This mechanism markedly enhances the concentration of drug at the target site than the passively targeted system or free drug. Generally, it is also termed as ligand-mediated targeting because various kinds of the ligand can be linked to the surface of the carrier system through which these are captured by the receptors of the targeted cells (**Fig. 2(B)**). This perspective is intended to augment the interaction between the cells and the carrier system to increase the entry without varying the biodistribution. For active targeting, the receptors on the desired cells should be expressed unvaryingly. Ligands may be monoclonal antibodies (mAbs), antibody fragments or non-antibody. The binding capacity of the ligands affects penetration because of the “binding-site barrier” ([Adams et al., 2001](#); [Saraf et al., 2020b](#)). The increased cellular internalization is responsible for the anti-cancer potential of nanocarriers by active targeting rather than enhanced tumor accumulation. Ligand anchored nanocarriers

result in direct cell kill, along with cytotoxicity to the cells of cells that are at the tumor periphery and are independent of the tumor vasculature. The transferrin receptors are approximately 100 folds more overexpresses than in the normal cells. Its extracellular accessibility, potential to internalize and chief role in the cellular pathology of cancer make transferrin receptor a fascinating target. Some other receptors such as folate, epidermal growth factor receptor (EGFR) and glycoprotein receptor are also present on cancerous cells (Danhier *et al.*, 2010; Attia *et al.*, 2019; Jain *et al.*, 2019b).

Stimuli-Responsive Delivery

Nanocarriers can uphold stealth function throughout the movement, upon reaching the tumor site. The conversion of the nanocarriers is prompted by the exceptional tumoral extracellular environment, either by internal stimuli (pH, redox, and enzyme) or by external stimuli (light, mechanical force, electric field, Photothermal, and magnetic field) permitting the release of the drug or the involvement with a particular target. The external stimuli can help to retain drugs within the nanocarrier and for the controlled release of the drug. Such types of smart delivery systems have a variety of applications in the field of biology, medicine, drug delivery, and biosensors. Various research studies have carried out on stimuli-responsive biopolymer composite for drug delivery. Such smart biopolymer matrix can be utilized in biological, medicinal, drug delivery and biosensing applications. Such intelligent polymers have found many applications in the fields of biology and medicine and can be used as sensors and biosensors for controlled and triggered drug delivery (Hu and Liu, 2010; Bajpai *et al.*, 2008; Jain *et al.*, 2018c; Prajapati *et al.*, 2020a). The design of the biopolymer matrix must ideally be easy to administer, should be capable to deliver the drug at the desired target site and the blend of the polymer should be biocompatible and non-toxic (Wei *et al.*, 2017).

Overview of Development Methods

The biopolymer matrix composite comprises the properties of two or more polymeric material to attain better physicochemical and biological properties while delivering the drug. Biopolymer-based composites have been developed by the use of various tactics. Out of them, some widely used methods are solvent casting (Park *et al.*, 2017), phase separation (Shao *et al.*, 2012), electrospinning (Bianco *et al.*, 2009; Ghosal *et al.*, 2018) and freeze-drying (Hottot *et al.*, 2004; Fig. 3). A detailed account of these methods is provided in Table 2.

Role of Exploited Biopolymers in Matrix Development

Biodegradable polymeric composites can achieve anti-cancer targeting via various mechanisms. This comprises delivery to the tumor cells enabled by extended circulation in the blood, capacity to enable transport across the endothelium to the tumor, and ligand-mediated targeting. Targeting tumor vasculature is a prime target as the tumor-associated neovasculature is a key to permitting the tumor to obtain enough oxygen and nutrients to allow growth. Besides, their biodegradability, biocompatibility, and non-immunogenicity make them a material of choice for anticancer drug delivery. Different types of biopolymers such as hyaluronic acid, chitosan, polylactic acid, and polylactic acid-co-glycolic acid, etc. are well reported for anticancer drug delivery (Prajapati *et al.*, 2019; Gulbake *et al.*, 2017).

Drug Delivery Applications of Biopolymer Matrix in Various Cancers

Breast Cancer

Bano *et al.* (2016) reported the promising result of chitosan (CS), bovine serum albumin (BSA), or carboxymethyl cellulose (CMC) and then coated with NiFe_2O_4 . The activity of composite was evaluated on the MCF breast cancer cell line. The outcomes of the study revealed that composite delivers a single combinatorial tactic to expand the biocompatibility and improve the relaxivity value. The outcomes powerfully reinforced the ability of BSA, CS and CMC composite to cancer cells. The prepared system i.e., BSA@NFs, CS@NFs and CMC@NFs can potentially be used as imaging probes while targeting MCF-7 cancerous cells. Song *et al.* (2018) fabricated the magnetic chitosan/alginate nanoparticle loaded with curcumin. A sustained release of drug was observed. Confocal fluorescence microscopy (CLSM) data revealed site-specific delivery of curcumin by applying the magnetic field. The cell sorting assay revealed that nanoparticles showed significant uptake capacity than free curcumin to the MDA-MB-231 cells. MTT assay revealed its potential cytotoxic effect on the MDA-MB-231 cells compared to HDF cells (Song *et al.*, 2018). In research, Bhunchu *et al.* (2016) for the delivery of curcumin diethyl disuccinate (CDD), worked to prepare chitosan/alginate composite nanoparticle CDD loaded chitosan/alginate nanoparticle depicted excessive toxicity toward breast adenocarcinoma cells (MDA-MB-231) (Bhunchu *et al.*, 2016). Chitosan/alginate composite nanoparticles were developed by Rahaiee *et al.* (2017) for the delivery of crocin. The cell viability evaluated on MCF-7 cells, the cell viability found to be decreased as the concentration of crocin increased. Though, a higher (10 mg/mL) dose of crocin caused tissue necrosis. Noticeable difference in cell mortality observed

Fig. 3 Overview of development methods: (A) Solvent Casting, (B) Phase Separation, (C) Electrospinning, and (D) Freeze Drying. (C) Reprinted with permission from Ghosal, K., Chandra, A., Praveen, G., et al., 2018. Electrospinning over solvent casting: Tuning of mechanical properties of membranes. *Scientific Reports* 8, 1–9.

Table 2 Methods of biopolymer matrix composite development

Method	Remark	Reference
Solvent casting	- The solvent casting method is based on the dispersal of a porogen in a liquid or powder-based stuff. - The polymer solution is hardened either by solvent evaporation or cross-linking. - The powder is compacted using pressure and temperature. Porogen particles are then melted in a specific solvent, and then the structure is generated.	(Park <i>et al.</i> , 2017)
Phase separation	- In this method, the thermodynamic demixing of the polymer solution into the polymer-rich phase and polymer poor phase occurs at the time of cooling. - Further, polymer affluent phase solidifies, and polymer poor phase is removed. Sublimation was done to remove the solvent.	(Shao <i>et al.</i> , 2012)
Electrospinning	- Electrospinning is an economic technique. - It is governed by an electric field of high magnitude between electrodes, which are located in a polymer solution, and a collector with electric charges of opposite polarity. - The polymer solution pulled from a nozzle under gravity or by mechanical pressure united with an electric field (5–50 kV). - A polymer jet is produced as the surface tension of polymer droplet increases due to the electric field. - Then the solvent evaporated, resulting in the formation of solid nanofibers.	(Bianco <i>et al.</i> , 2009)
Freeze drying	- The freeze-drying tactic is applied at low temperatures, which is helpful for integrating heat-sensitive bioactive molecules in the polymer composite. - In this technique, the formation of ice crystals leads to the induction of porosity via sublimation and desorption. - This method comprises a dispersed water phase and a continuous organic phase having biodegradable polymer which will then produce the composite. - At the time of freezing, the solution of the polymer is chilled. - Subsequently, the solvent's ice crystal forms, therefore compelling polymer molecules to aggregate in interstitial spaces. - Then, to remove the solvent the pressure is applied which will lower than the equilibrium vapor pressure. - The sublimation of the solvent produces the dry polymer composite.	(Hottot <i>et al.</i> , 2004)

between blank and drug-loaded nanoparticles. The cell viability of MCF-7 cells was found to be concentration-dependent (Rahaiee *et al.*, 2017). Qin *et al.* (2018) prepared paclitaxel and epirubicin loaded mPEG-g-CS coated PLGA NPs. No effect on the cell viability of MCF-7 cell and HUVEC (human umbilical vein endothelial cells) were seen in the case of blank nanoparticles. A significant reduction in cell viability was seen might be due to an increase in drug concentration. In comparison to free drug, the viability of both the cell line when treated with core shell nanoparticles found to be reduced confirming the potential of drug-loaded nanoparticles. Both the drugs when used together showed a synergistic effect. The maximum cytotoxicity of core-shell nanoparticles can be accredited to the greater anti-tumor's consequence of the mutual chemotherapy when compared with a single drug (Fig. 4; Qin *et al.*, 2018).

Colon Cancer

Hung *et al.* (2019) developed AuNPs/biopolymer composite to deliver doxorubicin (DOX) to the colon. AuPPPyA and AuPPPyB two composite with different drug loads were developed. The rate of tumor inhibition was near 46.2% and 66.4% respectively for AuPPPyA and AuPPPyB which was significantly higher than DOX alone (30%). MTT assay confirmed that DOX-AuPPPyA and DOX-AuPPPyB showed more cytotoxicity to the DLD-1 and HCT-116 colorectal cancer than free DOX confirming their potential for colon cancer treatment (Hung *et al.*, 2019). Sun *et al.* developed nanocomposite beads by the use ZnO/carboxymethyl cellulose/chitosan. 5-FU loaded to these beads showed sustained release of drug in colonic simulated fluid which was dependent on the concentration of composite material (Sun *et al.*, 2019a). In another study, alginate/chitosan/kappa-carrageenan (Alg/Cs/kC) composite microbeads loaded with 5-fluorouracil (5-FU) were developed by Sun *et al.* (2019b) 5-FU release was found to be lessened by adding supplementary kC layer from 14% to 7% in the dual-layered Alg/Cs/kC microbeads. Moreover, the release markedly enhanced under simulated intestinal and colon environments. Rajan *et al.* (2013) prepared nanocomposite by combining chitosan-PEG-gelatin polymer for delivery of 5-FU. The cytotoxicity was assessed on the colon cancer cell line (COLO-205 and HT-29). The developed nanosystem was found to be less cytotoxic compared to the 5-FU after incubation for 3–12 hrs. No significant variances were seen between the negative control and unloaded nanoparticles after incubation for 24. The cytotoxicity of the carrier system was reliant on the concentration of the drug (Rajan *et al.*, 2013). Guar gum modified stimuli-responsive nanocomposite for colorectal cancer treatment was developed by Kumar *et al.* (2019). The study described a strong green-emitting core-shell photoluminescent upconversion nanocrystals (CSGU) designed to synergistically accomplish stimuli-responsive i.e., enzyme and photodynamic prompted delivery of the drug for boosted therapeutic consequences on HT-29 colon carcinoma cells in vitro (Kumar *et al.*, 2019).

Lung Cancer

Zhang *et al.* (2019) prepared the hyaluronic acid/ chitosan nanoparticles for the delivery of siRNA to the lung cancer cells. The results exhibited efficient delivery of siRNA to A549 cells and repressed cell proliferation by downregulating the target gene BCL2. In vivo data exposed that the nanoparticles delivered a significant concentration of siRNA to the tumor, ensuring the inhibition of tumor growth (Zhang *et al.*, 2019). Arya and Katti (2015) prepared the composite particle of paclitaxel and topotecan loaded Poly (d, l-lactide-co-glycolide)-chitosan and evaluated their potential for NCI-H460 lung cancer cell line. Drug loaded composite particles revealed improved cell death of NCI-H460 tumoroids then the additive effect of paclitaxel and topotecan when compared individually (Arya and Katti, 2015). Baspinar *et al.* (2019) prepared paclitaxel loaded zein nanoparticles with or without the use of chitosan. The efficacy was evaluated on the A549 lung cancer cell line. The cytotoxicity exposed that 10 nM concentration of PTX concentration was enough to reduce the viability of cells to 35% in the case of nanoparticles without chitosan and 25% in the case of nanoparticles with chitosan. The maximum concentration (50 nM) was found to decrease the viability to 15% and 20% in the case of nanoparticles without chitosan and in the case of nanoparticles with chitosan, respectively (Baspinar *et al.*, 2019).

Cervical Cancer

Das *et al.* (2010) prepared composite nanoparticles from alginate (ALG), chitosan (CS), and pluronic for the delivery of curcumin. The cytotoxicity was evaluated on the HeLa cell line and at the concentration of 500 µg/mL nanoparticles found to be nontoxic (Fig. 5(A)). Curcumin showed concentration-dependent cell viability (Fig. 5(B)) and the projected half-maximal inhibitory concentration values for free and encapsulated curcumin was found to be 13.28 and 14.34 µM, respectively (Das *et al.*, 2010). Karimi *et al.* (2013) designed the nanoparticles of chitosan and albumin for the efficient delivery of genes. The cell viability potential was measured on the HeLa cell line. Alb-CS-DNA nanoparticles with 10 µg/mL concentration revealed 85% cell viability. The results were then compared with chitosan (Fig. 5). In the case of albumin cell viability 100% suggesting that albumin can promote biocompatibility. The cellular uptake study showed high Alb-CS-DNA nanoparticle by the cells (Karimi *et al.*, 2013).

Brain Cancer

Bazzazzadeh *et al.* (2020) for the delivery of temozolomide and paclitaxel developed poly(acrylic acid) grafted-chitosan/ polyurethane/ magnetic MIL-53 metal-organic framework composite. The cell viability Bax expression was evaluated on U-87 MG glioblastoma cancer cells. The results revealed that magnetic MIL-53 NMOFs loaded- PA-g-CS/PU/TMZPTX nanofibers can be effective for targeted anticancer

Fig. 4 Cell viabilities of NPs: (A–D) Effects of blank NPs on the viability and (E–H) Effects of drug loaded NPs on the viability of MCF-7 cells and HUVEC cells. Reprinted with the permission from Qin, J., Wei, X., Chen, H., *et al.*, 2018. mPEG-g-CS-modified PLGA nanoparticle carrier for the codelivery of paclitaxel and epirubicin for breast cancer synergistic therapy. *ACS Biomaterials Science & Engineering* 4, 1651–1660.

Fig. 5 Cytotoxicity assay: Cell viability of HeLa cells exposed to different concentrations of (A) blank ALG-CS-PF127 NPs and (B) free and encapsulated curcumin. Reprinted with permission from Karimi, M., Avci, P., Mobasseri, R., Hamblin, M.R., Naderi-Manesh, H., 2013. The novel albumin–chitosan core–shell nanoparticles for gene delivery: Preparation, optimization and cell uptake investigation. *Journal of Nanoparticle Research* 15, 1651.

drug delivery with apoptosis of 49.6% of U-87 MG glioblastoma cells (Bazzazzadeh *et al.*, 2020). Parmar *et al.* (2018) studied to develop polylactic acid co glycolic acid (PLGA) nanoparticles for the delivery of methotrexate (MTX) by conjugating transferrin. A biphasic drug release pattern was observed. Initially in 8hrs, > 35% drug release was observed and then sustained release (65%) by the end of 168 hrs. cellular uptake (quantitative) evaluation confirmed a collinear dependence on the concentration drug-conjugate. The tumor spheroid volume was significantly reduced when folic acid along with transferring conjugated on polysorbate 80 (P80) coated nanoparticles (P80-Mtx-Tf-FA-PNPs). The ex vivo cytotoxicity was evaluated on C6 glioma cell by SRB assay. P80-Mtx-Tf-FA-PNPs showed greater cellular cytotoxic effect when compared with another formulation group. At the concentration of 100 μM, the formulation incubated for 72 hrs resulted in 100% cell death of the cellular population. This might be attributed to the endocytosis by transferrin and folate receptor (Parmar *et al.*, 2018). Meenach *et al.* (2010) developed polyethylene glycol-based hydrogel nanocomposite for the hyperthermia. Magnetic PEGMMA/PEGDMA hydrogel nanocomposites can be effective in thermal cancer therapy via remote heating. Fig. 6 approves the potential of these experimentations, M059K glioma cells. The cells heated with hydrogel composite displayed discrete cell death at the center and an interface, while the favorable morphology was observed by the control group. On the other side, the IR images exhibited the final temperatures the cells were exposed to. Overall, these results show the ability of the gels to kill cancer cells without the magnetic field causing harm (Fig. 6; Meenach *et al.*, 2010).

Miscellaneous

Alemдар (2016) fabricated gelatin/alginate/hyaluronic acid composite film for the delivery of 5-FU. The cytotoxicity was evaluated on L929 fibroblast cells by WST-1 assay. No significant variation detected between the composite films w/out BA and control sample revealed that neat Gel/SA/HyA and Gel/SA/HyA/5 v. %BA did not cause a cytotoxic effect on the viability of L929 cells (Alemдар, 2016). Patiño-Ruiz *et al.* (2020) prepared chitosan/alginate nanodisk (Cs-Al nanodisks) and assessed their potential for prostate cancer. The Cs-Al nanodisks evaluated for cytotoxic effect on two different PWR-1E (human prostate cells line) and PC-3

Fig. 6 M059K glioblastoma multiforme/hydrogel heating results: Images (a-i) represent fluorescent microscopy images after Live/Dead assay of M059K cells, where (a-b) are at the center of the Petri dish, (d-f) are at the interface between live and dead cells and (g-i) are at the outer edge, unaffected by heat. The first column of images are for cells exposed to a DM gel (50 mol.% PEG200MMA, 50 mol.% TEGDMA) at 297 kHz and 25 kA m⁻¹ for 5 min, the middle column is of cells exposed to an AMF only at 297 kHz and 25 kA m⁻¹ for 5 min and the right column is of cells not exposed to gels or an AMF. Images (j & k) represent IR images after the cells had been heated with the gel for 5 min (j) and exposed to an AMF for 5 min (k). Represented with the permission from Meenach, S.A., Hilt, J.Z., Anderson, K.W., 2010. (Caucasian prostate cell line). More than 80% of cell viability revealing low inhibition and defining the Cs-Al nanodisk as an optimistic technique for controlled delivery (Patiño-Ruiz *et al.*, 2020).

Conclusion and Future Scene

Biopolymers are material of choice for the purpose of anticancer drug delivery due to their distinguished properties than other materials. Biopolymers are biodegradable, biocompatible and non-toxic to the cells. Previously, blends of the biopolymers have been extensively used for tissue engineering, drug delivery and other medical applications. The blends prepared in the combination of the proper ratio can improve its mechanical strength for the fabrication of matrix composite. Improved biopolymers with distinct polymeric sections can affect properties altering their sensitivity, cellular uptake, and drug release. The functional groups existing on the surface of biopolymers can be exploited for crosslinking and bioconjugation with cell-targeting agents. The size is of great importance for organ or tissue-specific targeting. The decisive goal would be to exploit the diagnostic evidence and therapeutic efficacy, lessen the time for diagnosis, and decrease the extent and incidence of invasive interventions.

The selection of a biopolymer depends on the physicochemical properties of the drug and the characteristics of the tumor cells. The loading of the drug in the carrier system and their prevention is a challenging task. Most of the drug molecules get degraded in various enzymatic environments. Different types of combinations can help overcome such drawbacks. It is also challenging to define the proper concentration of the polymer to fabricate the polymer matrix of desired properties. In order to monitor compatibility with living tissue or a living system for its toxicity, injuriousness, or physiological reactivity without causing immunological rejection like antigenicity needs effective in vivo and clinical tests or efficient biological models mimicking the uptake of released drugs. Future advances in the execution of a biopolymer matrix in therapeutics would embrace the ability to scale-up without forfeiting the exact control. The development of effective approaches for harvesting biopolymer matrix along with ethical concerns need to be prioritized. Computational models need to be unified to clarify the effects on the degradation profile, intra- and extra-cellular trafficking of polymeric nanoparticles for increased commercialization. Computer-based optimization can be done to define the specific amount of polymers to achieve the desired properties of the polymer blend.

Introduction

The prospects of nanotechnology and its prompt integration with the food/pharmaceutical field have led to the development of effectual nutraceutical/drug delivery systems with targeted release properties (Assadpour *et al.*, 2020). However, notwithstanding the accumulated attempts on the bioactive delivery systems, the poor applicability of encapsulation approaches have caused multiple hindrances, which set limits to their clinical applications (Peltonen, 2018; Rostamabadi *et al.*, 2019a,b). In this scenario, numerous promising nutraceutical candidates are admitting the fate of being adversely developed, owing to the insufficiency of some carrier matrices (Falsafi *et al.*, 2020b).

The prerequisites for the potential encapsulation of bioactives/drugs are the maximization of absorptive cellular uptake and physical/chemical stabilization of the therapeutics at all steps before reaching their destination (Abaee *et al.*, 2017; Jafari and McClements, 2017; Rostamabadi *et al.*, 2020a, 2019a). To design and develop carrier matrices equipped with these attributes, the focus of encapsulation strategy is on superior vehicles and materials for nutraceuticals delivery (Esfanjani and Jafari, 2016).

Nowadays, numerous novel and efficient biopolymer-based delivery matrices have been engineered through encapsulation technology to meet the ever-increasing demands of various fields. In this line, nature-inspired polysaccharides and proteins from plants, animals, and even microbial origins (such as bacteria, yeast, or microalgae) are extensively utilized as functional biopolymer matrices in the food and pharmaceutical realm (Aditya *et al.*, 2017; Assadpour and Jafari, 2019; Jacob *et al.*, 2018; Joye and McClements, 2014). Instances comprise plant- or microbial-derived polysaccharides e.g., gum arabic, pectins, chitosan, alginate, and xanthan gum. On the protein side, plant-derived proteins like soybean, pea, or canola and animal-based ones e.g., gelatins and whey proteins have found common application (Bolhassani *et al.*, 2014; Gupta and Nayak, 2015; Park *et al.*, 2017).

Recently, covalent and non-covalent protein-polysaccharide systems have gained a great deal of attention for the delivery and protect of a vast verity of bioactive ingredients (e.g., phenolics, carotenoids, volatile oils, flavors, etc.). Notwithstanding the fact that the polysaccharide and protein matrices individually possess a range of beneficial features, e.g., the potential to serve as thickening, stabilizing, or water-holding agents (Damodaran, 2005; Doublier *et al.*, 2000; Samant *et al.*, 1993), they can be made to assemble into hierarchically higher-ordered arrangements, which can provide novel (bio)functionalities. These properties render both covalent and non-covalent protein-polysaccharide systems as effective pair biopolymers for the development of novel nutraceutical formulations. In this line, Table 1 summarizes the application fields of covalent and non-covalent protein-polysaccharide systems. The covalent linkage is attained by a Maillard-type reaction lead to the formation of protein-polysaccharide conjugates with strong heat stability (Fechner *et al.*, 2007; Shah *et al.*, 2012b; Yi *et al.*, 2014). In a conjugate system of protein-polysaccharide, the polysaccharide fraction typically endows potent steric and sometimes electrostatic repulsion, and the protein molecule of the conjugate could be attached to hydrophobic surfaces. Nevertheless, the reaction circumstances, e. g., pH or temperature, should be precisely controlled to attain a desirable reaction (George *et al.*, 2020; Li and Gu, 2014; Shah *et al.*, 2012a; Xu *et al.*, 2013). In the case of non-covalent systems of proteins and polysaccharides, the driving forces include electrostatic, hydrophobic, H₂ linkage, as well as Van der Waals interactions, which induce the generation of coacervates (Eratte *et al.*, 2015; Pham *et al.*, 2020, 2021).

This article highlights the applicability of polysaccharide-protein systems fabricated through both covalent and electrostatic interactions in designing nutraceutical delivery systems to exploit their benefits in nano/micro-encapsulation, shield, and delivery of different nutraceuticals.

Proteins

Food-grade proteins have revolutionized bioactive delivery by offering a myriad of unique physical/chemical and structural features to delivery vehicles (Gaber *et al.*, 2018; Weiss *et al.*, 2019). Due to the presence of multiple functional units in the primary sequences of polypeptides, protein-based matrices could be utilized to create diverse interactions with bioactive agents, providing a range of possibilities for nutraceutical delivery (Elzoghby *et al.*, 2011, 2012). Protein-based carriers are acceptable as metabolizable nature-inspired components, as hydrolysis of protein molecules by gastrointestinal enzymes lead to the generation of bioactive peptides, which might exert various physiological influences in vivo (Chen *et al.*, 2006). A number of strategies have been employed to design protein-based delivery systems with outstanding release manners, bioactivities, targeting capacity, as well as safety (Eratte *et al.*, 2015; Sriprabhom *et al.*, 2019; Yang *et al.*, 2015a).

Proteins can inherently hinder the flocculation of emulsion particles as a result of their high attitude to adsorb onto the hydrophilic-hydrophobic interfaces and creating a comparatively thin adsorbed cover by subsequent unfolding (approximately 2–6 nm) and

Table 1 Some examples concerning the application fields of protein-polysaccharide pair systems

Field	Usage	Reference
Medicine/ pharmacy	● Drug/gene delivery. ● Extraction or purification of different compounds	(Gaber <i>et al.</i> , 2018; Nitta and Numata, 2013)

generating electrostatic and steric stabilization (Dickinson, 2010; Jacob *et al.*, 2018; Yang *et al.*, 2015b). The van der Waals attractive forces among particles in a colloidal system dominate the electrostatic repulsion, simultaneously the electric charge of protein molecules is the main is the most important reason that jeopardize the stability of colloidal system. At the isoelectric point (pI) the positive and negative charges are balanced, diminishing repulsive electrostatic forces and leading to the aggregation and/ or precipitation (Vadavik and Christian, 2008). Furthermore, numerous studies on proteins revealed how environmental conditions e. g., heat treatment, pH value, ionic strength, as well as polymer concentration affect the pI (Liu *et al.*, 2016; Sripabloom *et al.*, 2019).

Polysaccharides

Naturally occurring polysaccharides are obtained from different resources from animal origins (e.g., chitosan), algal origins (such as alginate), plant origins (like pectin or guar gum), as well as microbial sources (e.g., xanthan gum or dextran) and have intrinsic bioactivity due to their anti-bacterial, anti-inflammatory, as well as mucoadhesive properties (Liu *et al.*, 2008; Reis *et al.*, 2006). Polysaccharides possess numerous reactive units, different molecular weights, plenty of chemical compositions, contributing to their diversity in configuration and in attribute (Rostamabadi *et al.*, 2019c,d). Polysaccharides could be grouped into two main classes including polyelectrolytes and non-polyelectrolytes; the former could be further classified into negatively charged polysaccharides (such as pectin, alginate, hyaluronic acid, etc.) and positively charged ones (e.g., chitosan) (Du *et al.*, 2004; Liu *et al.*, 2007). As nature-inspired components, polysaccharides are hydrophilic, biodegradable, greatly stable, low-cost, safe, and non-toxic. Polysaccharides mostly possess hydrophilic domains e. g., hydroxyl, carboxyl, as well as amino units that can create non-covalent linkages with biological tissues such as epithelia or mucous membranes, rendering bioadhesion (Falsafi *et al.*, 2018, 2019; Rostamabadi *et al.*, 2019c). It is noteworthy that the bioadhesive polysaccharides such as alginate, chitosan, starch, etc. could extend the residence time and improve the absorbance of entrapped bioactives in vivo (Lee *et al.*, 2000; Rubinstein, 2000; Sinha and Kumria, 2001).

Protein-Polysaccharide Systems

Engineering protein-polysaccharide systems for nutraceutical delivery has attained momentum by virtue of their biochemical/ biophysical attributes over synthetic delivery cargos, i.e., biocompatibility, scalability, tunability, as well as lack of toxicity (Doublier *et al.*, 2000; Schmitt and Turgeon, 2011). These structures, have been widely implemented to develop an efficient host for a range of nutraceutical molecules such as curcuminoids, carotenoids, vitamins, polyphenols, essential oils, etc. (Gaber *et al.*, 2018; Gentile, 2020). In this line, following sections will be discussed the application of covalent and electrostatic protein-polysaccharide systems for nutraceutical delivery.

Conjugated Systems

Covalent interactions between proteins and polysaccharides are greatly specific and strong, creating a permanent, irreversible protein-polysaccharide linkage (Shah *et al.*, 2012b; Yi *et al.*, 2014). This interaction is recognized as protein-polysaccharide glycosylation, which chemically created by amino residues of the protein molecule and carboxylic units of the polysaccharide moiety, establishing a covalently bound amide (George *et al.*, 2020; Li and Gu, 2014). The main reason for such reaction is principally relevant to the presence of lysine residues, which induces a Maillard-type reaction with the reducing sugars of the polysaccharide molecule, upon properly low water-activity and heat treatment at an incubation period of around a few hours (Akhtar and Ding, 2017; De Fenoyl *et al.*, 2018; Zhang *et al.*, 2020).

Contrary to the non-covalent interactions, the protein-polysaccharide conjugates or covalent systems are not responsive to ionic strength and pH variations. Interestingly, the formation of glycosylated protein-polysaccharide conjugates can be considerably

influenced by the length of the polysaccharide chain and the nature of the protein molecule. In the view point of protein structure, the unfolded proteins like casein typically react more promptly with polysaccharide structure than folded ones e.g., lysozyme (Dai *et al.*, 2018; George *et al.*, 2020; Lopes *et al.*, 2019; Wijaya *et al.*, 2017).

One substantial restriction of the conjugation process could be the loss of protein functionality, as most of the lysyl unites are covered by the polysaccharide moiety, especially concerning conjugates of proteins with mono or oligosaccharides. Nonetheless, the Maillard conjugates of proteins and polysaccharides typically demonstrate an excellent emulsifying capacity, anti-microbial property, and even heat stability (Gentile, 2020).

Electrostatic Complexes

The complexation mechanism between macromolecules mainly stems from the electrostatic interactions between diverse oppositely charged biopolymers, especially a protein and a polysaccharide. The soluble complexes of protein-polysaccharide pairs then continue the aggregation and reduction the free energy of the system until their size/surface characteristics offer a way to insolubilization, consequently causing liquid-liquid phase separation and coacervation through non-covalent and H-bonding interactions (Dai *et al.*, 2018; Schmitt and Turgeon, 2011; Weinbreck *et al.*, 2004a). Protein chain carries a negative or positive surface charge relying on the pH range of the protein-polysaccharide system. The positive/negative zeta potential of the protein molecule oriented from the presence of various amino acid groups within the protein structure and their mode of ionization at diverse pHs (de Oliveira *et al.*, 2020; Yeo *et al.*, 2005a). Food proteins with a pI approximately 5 could create complex coacervates with anionic polysaccharides e.g., pectin (with pKa 3.5) in the intermediate pH range, where both macromolecules possess opposite net charges: pH below the pI of the protein but above the pKa of the polysaccharide (Eratte *et al.*, 2015; Koupantsis *et al.*, 2014).

The electrostatic complexes between proteins and polysaccharides are mainly affected by a range of parameters, including pH and ionic strength of the medium, biopolymer concentration or molecular weight, and protein-to-polysaccharide ratio (Aylanc *et al.*, 2020; Esfahani *et al.*, 2019). A number of other factors like temperature, pressure, flexibility, charge density, and even stirring have also been demonstrated to affect the coacervation phenomenon (Chen *et al.*, 2018; Xie *et al.*, 2019).

It is worthwhile to note that there are several instances in the literature where the two polymeric poly-ions are proteins (Clarke *et al.*, 2006; Croguennec *et al.*, 2017; Nigen *et al.*, 2007). Intriguingly, same-charged complex coacervates have been also stated even between two positively charged polyelectrolytes as a result of suppressing long-range electrostatic repulsion (Kim *et al.*, 2016). Generally, coacervates are defined as reversible structures, which form or segregate as the polymeric solution and/or environmental circumstances are changed (Cooper *et al.*, 2005; Kayitmazer *et al.*, 2013; Schmitt and Turgeon, 2011).

Characterization Approaches of Protein-Polysaccharide Systems

In the case of glycosylated protein-polysaccharide conjugates, electrophoresis is one of the most widely utilized approaches for characterization of protein-polysaccharide systems. The synthesis of conjugate structures through the covalent bonds between the amine units of the protein molecule and the carbonyl/carboxyl units of the polysaccharide moiety might be corroborated by using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) technique (Fechner *et al.*, 2007; Shah *et al.*, 2012a; Yi *et al.*, 2014).

A number of methods have been employed to investigate the degree of protein modification and the extent of the Maillard reaction. The latter is determined by the average number of lysine residues, which react with polysaccharide molecule. In this context, the o-phthalaldehyde (OPA) is a colorimetric assay for indirect determination of the extent of the Maillard process relying on the reaction between the OPA and the free amine units of the protein molecule (Kim and Shin, 2020; Tu *et al.*, 2020). The 2,4,6-Trinitrobenzenesulfonic acid (TNBS) test is another prompt and sensitive chemical method applied to quantify the free primary amino units. The reaction between TNBS and amine groups lead to the generation of a highly chromogenic product, which could be measured at 335 nm (Dong *et al.*, 2020; Shi *et al.*, 2019). The extent of the Maillard reaction can also be quantified using furosine assay (ϵ -N-furoylmethyl-L-lysine), followed by acid hydrolysis of the Maillard reaction products (Li *et al.*, 2020; Michalska *et al.*, 2016).

Other approaches commonly utilized in conjugate characterization are circular dichroism (CD), dynamic light scattering (DLS), Matrix Assisted Laser Desorption Ionization-Time of Flight-Mass Spectrometry (MALDI-TOF MS), fluorescence spectroscopy, imaging approaches (e. g., atomic force microscopy (AFM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM)), fourier transform infrared spectroscopy (FTIR), and colorimetric assays (Rostamabadi *et al.*, 2020b; de Oliveira *et al.*, 2016).

Electrostatic protein-polysaccharide as potential bioactive carriers are also characterized through several experimental approaches, as summarized in Table 2.

Application of Protein-Polysaccharide Systems for Encapsulation of Different Bioactive Compounds

Biopolymeric delivery systems based on covalent conjugates and complex coacervates have been widely utilized to develop micro/nanocapsules of unique (bio)functional attributes e.g., providing a homogeneous distribution of mainly non-polar ingredients in polar media, enabling controlled bioactive release, as well as hindering degradation of sensitive bioactive molecules (Assadpour

X-Ray diffraction (XRD) analysis Imaging approaches	- Crystallographic study of the complexes. - Application of AFM, SEM, and TEM to study morphological properties, size, and homogeneity of the protein-polysaccharide particles.	Falsafi <i>et al.</i> (2018) Falsafi <i>et al.</i> (2020a)

et al., 2017; Assadpour and Jafari, 2018). One of the main goals of the encapsulation strategies is to shield nutraceuticals from environmental stresses e.g., oxidation, extreme pHs/temperatures, digestive enzymes, etc. (Rostamabadi *et al.*, 2019c, 2020c). This is particularly crucial when developing (bio)functional food products or other bioactive formulations to ensure that the

nutraceutical ingredients preserve their bioactivity/(bio)functionality through processing conditions, storage time, and more importantly in vivo (Boostani and Jafari, 2020; Dima *et al.*, 2020). Such biologically active agents include liposoluble carotenoids (Rostamabadi *et al.*, 2019e), hydrophobic/hydrophilic vitamins (Hsu *et al.*, 2019), essential oils (Esfahani *et al.*, 2019), flavors (Xiao *et al.*, 2019), curcuminoids (Park *et al.*, 2018), oils high in essential ω -3 fatty acids (Chen *et al.*, 2018), etc. Protein-polysaccharide conjugates and coacervates has also been employed to entrap other bioactives i.e., probiotics (Eratte *et al.*, 2015), anti-bacterials (Amara *et al.*, 2017), as well as agricultural components (Dai *et al.*, 2017; Weiss *et al.*, 2019).

Phenolic Compounds

In a recent study by Xie *et al.* (2019), curcumin was incorporated into ovalbumin- κ -carrageenan nanocomplexes (at pH 2.6–3.4) with a slow release upon gastric phase and a potent capability for delivery in the simulated intestinal tract. More recently, Fan *et al.* (2018) produced spherical Maillard conjugate nanoparticles based on bovine serum albumin (BSA) and dextran for curcumin delivery and indicated that the curcumin-encapsulated nanoparticles had higher oxidative and pH stability (at pH 2.0–7.0) as compared to free bioactive. It is worth mentioning that the excellent physicochemical stability of the protein-polysaccharide nanoparticles was probably related to the steric stabilizing impact of the water-soluble dextran conjugated to the protein matrix, designing a dextran-shell BSA-core configuration. The dextran shell properly repelled the proteolysis mechanism in both gastric and intestinal phases, and could improve the physical/chemical stability of the embedded curcumin upon digestion. Wang *et al.* (2016), investigated the behavior of mixtures of BSA and dextran under dry heating of the protein-polysaccharide powder (for 48 h at $\sim 60^\circ\text{C}$ and relative humidity of 79%) for the encapsulation and protection of curcumin-loaded O/W emulsions. The authors noted that the emulsion stability hinges upon both the bioactive concentration and oil volume fraction. Curcumin-loaded emulsions was found to be highly stable at both neutral and acidic conditions probably due to the proper integration into the vehicle and suitable cohesiveness of the interfacial film, preventing the bioactive degradation, precipitation, as well as diffusion to aqueous part. Moreover, the presence of conjugate systems in curcumin-enriched carriers could potentially enhance (4.8 times) the oral bioavailability of the bioactive in mice and promote its absorption in vivo. Dai *et al.* (2018) also designed ternary complexes of zein, propylene glycol alginate, and surfactant (lecithin or rhamnolipid) using anti-solvent co-precipitation method (at pH 4.0) and studied the potential application of these systems for delivery of curcumin and increasing its (bio)stability and bioaccessibility. It was illustrated that the presence of surfactant in complex particles could increase both photo-stability and bioaccessibility of the bioactive. The bioactive bioaccessibility enhanced from 25% when only protein was utilized as vehicle matrix to approximately 80% in the complex particles.

In a study from Zhou *et al.* (2012), a novel type of complex coacervation core micelles based on gelatin-dextran conjugates was utilized for effectual delivery of tea polyphenol. The protein-polysaccharide blend was dry-heated at 60°C upon relative humidity of 79% (24 h) to prepare Maillard-type conjugates. Subsequently, the bioactive solution was added to the produced conjugates at a desired pH value to generate complex coacervation core micelles (at room temperature). Contrary to the pure protein or non-heated protein-polysaccharide blends that displayed an obvious precipitation in the presence of the bioactive polyphenol (Fig. 1(A–C)), the polyphenol-loaded protein-polysaccharide conjugates at pH 5.0 developed a homogenous dispersion of narrow particle size distribution (Fig. 1(A, B)). It was postulated that the polysaccharide fraction in the conjugate system by virtue of its stabilizing capacity through the steric hindrance effects caused a lower aggregation of the protein-polyphenol insoluble core. Li and Gu (2014) fabricated self-assembled ovalbumin-dextran conjugate nanoparticles to encapsulate and promote the bioavailability of bioactive (–)-epigallocatechin gallate (EGCG). The conjugate was blended with the bioactive solution at pH 5.2 following heating at 80°C for about 1 h and the self-assembled nanoparticles was further cross-linked by glutaraldehyde at ambient condition for ~ 24 h. The bioactive-entrapped protein-polysaccharide nanostructures were spherical in morphology with loading efficiencies and particle sizes of $\sim 23\%$ – 30% and 285–339 nm, respectively. Interestingly, the apparent permeability coefficient of the bioactive on Caco-2 monolayers was considerably enhanced following encapsulation.

Carotenoids

As one of the most important carotenoids, β -carotene was entrapped into conjugate nanoparticles based on β -lactoglobulin and dextran using a homogenization-evaporation technique to increase its solubility, heat stability, and even bioavailability (Yi *et al.*, 2014). The carotenoid-loaded nanoparticles had potent pH-stability against aggregation upon in-vitro and showed notable release rate and permeability coefficient on Caco-2 cells. β -carotene has been also suitably embedded into whey protein-beet pectin conjugates, where the pH range, metal chelator, free radical scavenger, as well as interfacial properties influenced the carotenoid oxidative stability (Xu *et al.*, 2013). Xu *et al.* (2014) used a whey protein-beet pectin conjugate system for β -carotene encapsulation and clarified that the biostability of conjugate-stabilized emulsions i.e., resistivity to droplet coalescence or flocculation dramatically promoted during in vitro digestion. In another attempt, an O/W emulsion stabilized by casein-dextran conjugates was utilized to encapsulate bioactive lutein. The authors revealed the high stability of designed emulsions to isoelectric flocculation at pHs from 3.0 to 7.0, owing to the capability of the dextran matrix to generate strong steric repulsions overcoming any attractive interactions in the system. However, the application of Maillard conjugates did not influence the carotenoid bioaccessibility (Gumus *et al.*, 2016). Jain *et al.* (2016) demonstrated that β -carotene-embedded casein-gum tragacanth coacervates cross-linked with genipin successfully fabricated at pH 4.35 and protein: polysaccharide ratio of 2:1 (Jain *et al.*, 2016). The prepared

Fig. 1 Images of the gelatin-polyphenol blend (A); gelatin-dextran-polyphenol blend (B); and the complex coacervation core micelles comprised of the gelatin-dextran conjugates and polyphenol (C) (at protein to polysaccharide weight ratio of 1:1 and pH 5.0); TEM (A₁) and SEM (B₁) micrographs of the complex coacervation core micelles comprised of the gelatin-dextran conjugates and polyphenol. Reproduced from Zhou, H., Sun, X., Zhang, L., *et al.*, 2012. Fabrication of biopolymeric complex coacervation core micelles for efficient tea polyphenol delivery via a green process. *Langmuir* 28 (41), 14553–14561. Available at: <https://doi.org/10.1021/la303062j>.

microcapsules possessed particle size of $\sim 160 \mu\text{m}$, encapsulation efficiency of $\sim 79\%$, as well as coacervates yield of $\sim 83\%$. As compared to β -carotene dispersed in oil, the engineered coacervates could powerfully inhibit the degradation and lipid oxidation of the carotenoid during the storage time (2 months). In another study, a lipid extract rich in astaxanthin (obtained from shrimp waste) was encapsulated in gelatin-cashew gum complexes with high water solubility of ~ 28.6 and relatively low entrapment efficiency of around 60% (at pH 4.0–4.5) (Gomez-Estaca *et al.*, 2016). The coacervation process preserved about 47% of the bioactive following 43 days; whilst, the free carotenoid was almost completely decomposed (approximately 9% left). The astaxanthin-loaded freeze-dried microcapsules also incorporated in plain yogurt sample (as a model food matrix) with great coloring capacity, as the corresponding orange color was homogeneously dispersed through the food system and no indication of phase separation was detected.

Bioactive Vitamins

Other biologically active ingredients have also been embedded in protein-polysaccharide conjugates and coacervates. For example, the possibility of stabilizing double emulsions (water-in-oil-in-water type, W/O/W) using sodium caseinate-dextran conjugates to enhance the stability and release properties of vitamin B₁₂ was investigated by Fechner *et al.* (2007). As compared to the sodium caseinate-stabilized emulsions, the double emulsions stabilized by Maillard conjugates indicated smaller size distribution and better pH-stability (at pH 4.0) mainly due to the presence of an additional biopolymer layer around oil droplets and thus leading to better steric stabilization and hindering emulsion particles from aggregation/coalescence. Moreover, the vitamin release was dramatically diminished following acidification, heating, as well as storage period when the protein-polysaccharide conjugates

were applied as an emulsifier, resulted in the formation of a stable interfacial layer presented by the sodium caseinate-dextran system. This system could be effectual for the development of functional food products to alleviate obesity through decreasing stomach emptying rate and energy uptake. Besides, the superior resistivity of Maillard conjugates vs. enzymatic digestion in the upper parts of the gastrointestinal tract (stomach or small intestine) renders them excellent candidates for engineering colon-specific vehicles to avert/treat bowel ailments. In another study, [Comunian et al. \(2013\)](#) employed an emulsion system stabilized by gelatin-gum arabic coacervates to encapsulate anti-oxidant ascorbic acid with high encapsulation efficiency (approximately 98%), great physicochemical stability, controlled release upon specific circumstances, and potential of masking its acidic taste. [Chapeau et al. \(2016\)](#) utilized a spontaneous co-assembly of whey proteins (i.e., β -lactoglobulin and lactoferrin) as an effective (bio)vehicle for water-soluble vitamin B₉. The authors revealed the useful potentialities of such co-assembly for developing functional food products, proposing promoted health benefits, yet without applying non-food additives.

Essential Oils and Flavors

In a study from [Weinbreck et al. \(2004a,b,c\)](#), bioactive flavors and oils i.e., lemon, sunflower oil, and orange oil have been successfully encapsulated within gum arabic-whey protein coacervate complexes assembled at $\sim$ pH 4.0 with a loading capacity of more than 80%. The release properties of the flavored microcapsules in the model food system (Gouda cheese) demonstrated that the large complexes had the stronger release mechanism. Moreover, the covalently cross-linked particles exhibited the lowest release manner, which was probably related to the tough dense structure of the wall material and thus the difficulty of its breaking by chewing. In another study, the encapsulation of sweet orange oil in electrostatic complexes comprised of gum arabic-soybean protein isolate was potentially performed at a protein: polysaccharide ratio of 1:1 and pH $\sim$ 4.0 with encapsulation yield and encapsulation efficiency of around 90% and 80%, respectively ([Jun-xia et al., 2011](#)). Nevertheless, enhancing the bioactive content (20%–70%) diminished encapsulation yields/efficiencies and considerably. [Ocak \(2012\)](#) exploited an electrostatic complex of collagen hydrolysate-chitosan cross-linked with glutaraldehyde to entrap lavender oil and pointed out the high efficiency of both chitosan and crosslinker concentrations on release manner and encapsulation efficiency of the system. [Table 3](#) summaries some of the electrostatic biopolymer complexes utilized for micro/nanoencapsulation of essential oils and flavors.

In a study conducted by [Yang et al. \(2015a,b\)](#), the applicability of Millard reaction products based on soy protein isolate-soy soluble polysaccharide conjugates was investigated in stabilizing citral-loaded O/W emulsion. Upon thermal processing, storage period, and even in-vitro, the prepared emulsions exhibited a superior physical stability as compared to those formulated by the protein or polysaccharide solely. This was mainly as a result of potent emulsifying capability of protein and the steric stabilizing ability of polysaccharide moiety of the conjugate system, preventing droplets coalescence and promoting physical stability of the vehicle. The designed emulsions retained about 70% of the hydrophobic citral after 2 h in in-vitro gastric condition; whereas the bioactive citral released almost completely following 4 h in simulated intestinal phase.

Functional Oils and Essential Fatty Acids

By virtue of the health-benefiting effects of functional oils, there has been a tremendous increase in development of essential fatty acids (particularly ω -3-fatty acids) comprising food products, over the past several decades. Utilizing protein-polysaccharide complexes and conjugates, as protective carrier matrices, is an effective platform applied for O₂-sensitive oils. In this line, [Pham et al. \(2020\)](#) investigated the potential of flaxseed polyphenol-adducted flaxseed protein isolate-flaxseed gum coacervates to entrap flaxseed oil, where the protein was covalently adducted with hydroxytyrosol/polyphenol. The secondary configuration of the protein isolate was mainly comprised of β -sheet units, even more so after protein-polyphenol covalent conjugation. In comparison with the pure protein and protein-polyphenol adducts, coacervates formulated by flaxseed protein isolate-flaxseed gum, gum-protein-polyphenol, and gum-protein-hydroxytyrosol possessed notably lower β -sheet contents and higher random coil, indicating the less ordered structure of the developed coacervates. The produced microcapsules showed irregular-shaped structure with a wrinkled surface morphology at optimum pH of $\sim$ 4.6 and the protein-to-gum ratio of 6.0 ([Fig. 2\(A–C\)](#)). Coacervates fabricated by gum-protein-hydroxytyrosol showed the highest microencapsulation efficiency and the lowest surface oil of $\sim$ 95% and 1% w/w, respectively. However, the polyphenol-containing coacervates revealed the highest oxidative stability. [Gomez-Estaca et al. \(2016\)](#) displayed that the incorporation of a bioactive oil rich in ω -3 fatty acids within gum arabic/cashew gum-gelatin coacervates could increase the oxidative resistance of the loaded oil. The authors demonstrated that the cross-linked oil-loaded gelatin-gum arabic matrix maintained more stable oxidatively following crosslinking (sinapic acid/transglutaminase). However, there was no discrepancies between the oxidative stability of cross-linked gelatin-cashew gum and non-cross linked counterpart ([Gomez-Estaca et al., 2016](#)). [Liu et al. \(2010\)](#) reported that the oxidative sustainability of the ω -3 fatty acid containing flax seed oil remarkably improved upon its embedment into gelatin-gum arabic capsules ([Liu et al., 2010](#)).

Other Compounds

Intriguingly and with high relevance to (bio)functional food products, protein-polysaccharide systems have exhibited great potential to mask the unpleasant taste/flavor of various bioactive molecules ([Mendanha et al., 2009](#)). More recently, [Zeeb et al. \(2018\)](#)

Table 3 Some examples about the micro- or nanoencapsulation of essential oils and flavors using electrostatic protein-polysaccharide systems

Carrier matrix	Bioactive molecule	Comments	Reference
Flaxseed protein isolate-flaxseed gum complexes	Flaxseed oil	● Production of polyphenol-adducted protein-gum coacervates for encapsulation of the bioactive flaxseed oil. ● About 66%–80% and 5%–17% release of the entrapped oil in intestinal and gastric phases, respectively. ● The reduction of protein degradation in the intestinal stage following the polyphenol adduction. ● The highest (80%) and lowest (66.3%) oil release for gum-protein-hydroxytyrosol and gum-protein-polyphenol, respectively. ● The polyphenol-adducted coacervates was introduced as an efficient carrier agent for successful delivery of the payload to intestinal stage.	Pham <i>et al.</i> (2021)
Gelatin-gum arabic complexes	Garlic oil	● The highest loading efficiency and the maximum bioactive encapsulation yield of gelatin (type A/B)-gum at pH = 3.5 and 4.5, respectively. ● Generation of spherical-shaped coacervates with smooth topography and controlled bioactive release. ● The potential shield of bioactive-loaded coacervates from primary and secondary oxidation for 12 days at 45°C.	Siow and Ong (2013)
Chia seed protein-chia seed gum complexes	Chia seed oil	● The High lipolysis and release of chia seed oil from the spray-dried coacervates was highly dependent to shell composition. ● The highest release of the bioactive oil in gastric phase due to the hydrolysis of chia seed protein isolate and thus erosion of carrier matrix. ● The oil hydrolysis at intestinal phase following the action of pancreatic lipase. ● The oil hydrolysis of ~100% and 60% for free and encapsulated oil, respectively.	Timilsena <i>et al.</i> (2017)
Gelatin-gum arabic complexes	Bake flavor oil	● Effectiveness of both polyion concentration and homogenization rate on complex morphology, size distribution, and even the release mechanism of the flavor during heating. ● Fabrication of uni-vesicular structures through lower homogenization rates that released almost all of the loaded bioactive at 100°C or higher temperatures. ● Production of multi-vesicular bodies by high homogenization rates with a considerably lower release rate as compared to uni-vesicular ones. ● Improvement of the frozen baked foods by temperature-dependent release of the loaded flavors.	Yeo <i>et al.</i> (2005b)
Gelatin-gum arabic complexes	Allyl isothiocyanate	● Promoted sustained release of the payload following the tannic acid cross-linking. ● High encapsulation efficiency of the coacervate microcapsules.	Zhang <i>et al.</i> (2011)
Gelatin-gum arabic complexes	Xylitol	● Successful encapsulation of xylitol via a double emulsion approach followed by complex coacervation. ● Application of xylitol-loaded capsules in food products to extend their sweetness. ● Production of low soluble and small size complexes. ● Development of complex systems of high encapsulation efficiency for a hydrophilic payload.	Santos <i>et al.</i> (2015)
Soy protein isolate-Chitosan complexes	Algal oil	● Entropy/enthalpy dependency of the coacervation process. ● Viscoelastic solid behavior and gel-like structure of coacervates with high encapsulation efficiency. ● Improved oxidation stability of the bioactive oil following the encapsulation within coacervates.	Yuan <i>et al.</i> (2017)
Gelatin- Polyphosphate complexes	Fish oil	● Equivalent bioavailability of the bioactive oil following its incorporation within coacervate or soft-gel microcapsules.	Barrow <i>et al.</i> (2009)

(Continued)

Table 3 Continued

Carrier matrix	Bioactive molecule	Comments	Reference
Chitosan-xanthan/pectin complexes	Palm oil	- Superior yield, high encapsulation efficiency, and the unique release manner of lyophilized samples. - The best in vivo release of the bioactive was obtained for chitosan-pectin complexes. - The best release mechanism of the bioactive was observed in the yogurt for chitosan-xanthan micro-capsules.	Rutz <i>et al.</i> (2017)
Gelatin – Sodium Hexametaphosphate complexes	Tuna oil	- High encapsulation efficiency and yield of tuna oil after encapsulation. - Superior oxidative stability of the bioactive oil as compared to free oil.	Wang <i>et al.</i> (2014)
Cold water fish gelatine- gum arabic complexes	Sunflower oil	- Production of homogeneous protein-polysaccharide micro-capsules at room temperature. - Successful cross-linking of the coacervate shell via glutaraldehyde. - Possibility of continuous fabrication of capsules with controlled size and significantly low energy.	Piacentini <i>et al.</i> (2013)
Maillard conjugates of Glycated caseinate-glucose/ glucose sirup/ dextran	Fish oils	- Fabrication of conjugates via dry or wet heating reaction. - The improved oxidative stability of the bioactive loaded in caseinate-glucose sirup prepared through wet heating, resulted in the production of the redox active elements. - Higher stability of oil-loaded caseinate-glucose conjugate in comparison with the bioactive-containing caseinate-glucose sirup. - The increased stability to oxidation owing to the antioxidant property and emulsification capacity of protein-polysaccharide conjugates.	Drusch <i>et al.</i> (2009)
Whey protein isolate-maltodextrin Maillard conjugates	Eugenol	- Maillard conjugation using an emulsion-evaporation method. - Formation of heat stable dispersions at pH 3.0, 7.0, and even 5.0. - Enhanced both encapsulation and dispersion features at lower protein to polysaccharide ratios.	Shah <i>et al.</i> (2012a)
Whey protein isolate-maltodextrin Maillard conjugates	Lipophilic anti-microbial thymol	- Improved dispersibility, transparency, as well as thermal resistance of the nano-dispersions even at high bioactive content and pH ranges close to pI of the protein. - Promoted heat stability and solubility of the protein following the glycation process, as a result of steric stabilization induced by the polysaccharide moiety. - Encapsulation efficiency and mass yield of 35.7 g/100 g and 82.7 g/100 g, respectively.	Shah <i>et al.</i> (2012b)

successfully improved the perceived sensorial acceptance of novel *plant proteins* (i.e., pea and potato proteins) through the complexation with apple pectin (Zeeb *et al.*, 2018).

The significance of *probiotic bacteria* and their live delivery in vivo have also gained substantial attention nowadays. For example, co-encapsulation and assessment of probiotic bacteria (*Lactobacillus casei* 431) and ω -3 fatty acids (tuna oil) enclosed in complex coacervates of gum arabic-whey protein isolate was evaluated by Eratte *et al.* (2015). The authors illustrated that the viability of the encapsulated probiotic and the oxidative stability of ω -3 fatty acids significantly enhanced upon encapsulation within the protein-gum complex system. Microencapsulation of other probiotic bacteria e.g., *Lactobacillus paracasei* and *Lactobacillus paraplantarum* within whey protein isolate-gum arabic coacervates have also been reported previously (Bosnea *et al.*, 2017, 2014). In another study, *Lactobacillus rhamnosus* was entrapped into Maillard conjugates of whey protein-isomaltooligosaccharide by using cold gelation within an emulsion system and its survival was investigated following in vitro digestion (Liu *et al.*, 2016). The fabricated microspheres represented high encapsulation efficiency of ~89%, which was relevant to the hydrophilic-hydrophobic balanced glycoprotein in protein-polysaccharide conjugates and thus lower interfacial tension in system. Moreover, the buffer capacity of the protein molecules in firm network developed by conjugates, considerably decreased the diffusion rate of acid into the microspheres and increased the pH-senility of the probiotic.

Fig. 2 SEM micrographs of spray-dried capsules generated by flaxseed protein isolate-flaxseed gum (A), polyphenol-protein-gum (B), and gum-protein-hydroxytyrosol coacervates (subscripts 1 and 2 refer to scale bars of 20 and 10 μm , respectively). Reproduced from Pham, L.B., Wang, B., Zisu, B., Truong, T., Adhikari, B., 2020. Microencapsulation of flaxseed oil using polyphenol-adducted flaxseed protein isolate-flaxseed gum complex coacervates. *Food Hydrocolloids* 107, 105944. Available at: <https://doi.org/10.1016/j.foodhyd.2020.105944>.

Conclusion

By virtue of their unique attributes, the covalent and electrostatic protein-polysaccharide based vehicles are efficient delivery systems to nano/micro-encapsulate, shield, as well as deliver a vast variety of bioactive molecules in the food and medical/pharmaceutical sectors. This article has offered an overview of electrostatic complex or Maillard conjugate-stabilized vehicles, in which the protein-polysaccharide system offers a continuous and thick cover around the payload, lowering its degradability upon processing, storage time, utilization, as well as gastric transition. Therefore, the electrostatic complexes and Maillard conjugates of proteins and polysaccharides could be utilized as promising delivery systems to promote bioavailability and (bio)stability of nutraceuticals and formulate multi-functional products for the food/medicinal implementations. Nevertheless, more research studies are still required to characterize the protein-polysaccharide electrostatic complexes and Maillard reaction products to develop a biopolymer system of high functionality for designing a nutraceutical delivery system *in vitro/ in vivo*. It is also useful to note that the lower digestion rate of Maillard products can be useful in reducing the gastric discharging rate and the perceived energy from the foods, useful in treating the obesity patients. Besides, it seems that more *in vitro/ in vivo* investigations are required to consistently assess the efficiency of the covalent and electrostatic protein-polysaccharide based vehicles.

Introduction

Today, cancer is a serious threat to human health and one of the leading causes of death worldwide. The most common cancers are lung cancer, breast cancer, colon cancer and prostate cancer. The lack of appropriate treatment is the main reason for the high rate of cancer mortality. The treatments currently used to cure cancer including chemotherapy and radiation therapy are generally costly, ineffective, and cause painful side effects. On the other hands, removing cancer cells surgically is difficult, time consuming and painful. Hence, scientists are looking for cost-effective, efficient and targeted methods for diagnosing and treating cancer (Fu *et al.*, 2016; Wilson *et al.*, 2012; Fonseca *et al.*, 2015).

Drug is a natural or artificial product that is designed to cure or prevent certain diseases. Drugs are first prescribed and their therapeutic effects are shown after dispersal in the body and reaching the desired tissue or organ. Of course, the drug treatment process can also face challenges including negative effect of the drug on healthy tissues of the body, excretion of the drug by the body before affecting the damaged tissue and metabolism or destruction of the drug before reaching the damaged tissue. The best way to solve these problems is to prescribe a drug in very high doses so that at least a small amount of the drug reaches the desired tissue. But this method is not suitable at all. Because overexposure to the drug can cause irreversible side effects on other tissues. As a result, the scientific community is looking to develop tools for effective drug delivery (Morrow *et al.*, 2007; Vasir and Labhasetwar, 2005).

In recent years, many studies have been reported on the design, synthesis, and characterization of new substances as drug delivery systems to improve drug efficacy. With the help of these new systems, the safety of treatment increases and the correct amount of drug reaches the most appropriate place in the body at the correct rate. Using these systems can prolong drug activity and reduce drug side effects. Improving the performance of these systems requires the design of new materials as drug carriers. The carriers can release active drug compounds directly into cells and distinguish cancerous tissue from healthy tissue. This method can significantly improve the therapeutic efficacy of drugs. Because with this method, drugs accumulate only in the damaged tissue and the dose control and the release rate of drug can be adjusted. The release of targeted drug is able to achieve the desired curing effect with the least amount of drug (Yang *et al.*, 2011; Daum *et al.*, 2012; Alley *et al.*, 2010).

Today, nanotechnology has revolutionized the treatment of cancer by improving current cancer treatment methods as well as making new carriers and drugs. In other words, nanotechnology seeks to find an effective way to deliver drug molecules to target cancer cells without affecting healthy cells. It was found that using nanocarriers can be very effective to deliver drug molecules in a targeted manner without damaging healthy cells (Eliaz *et al.*, 2004; Shanmuganathan *et al.*, 2019; Kumari *et al.*, 2016).

Carbon nanotubes (CNTs) with unique physicochemical properties have received considerable attention particularly as effective drug nanocarriers, diagnostic tools and therapeutic agents (Guo *et al.*, 2017; Bianco *et al.*, 2005). Nowadays, composite materials based on polymeric hydrogels and CNTs (CNTs-based hydrogels) have received considerable attention of scientific community as innovative drug delivery systems. CNTs-based hydrogels with combining properties of both CNTs and hydrogels can be considered as drug delivery systems with improved mechanical, physicochemical, and biological properties (Prakash *et al.*, 2011).

Drug Delivery Fundamentals

The original idea of targeted drug delivery was first stated nearly a hundred years ago by Paul Ehrlich (Strebhardt and Ullrich (2008)). Cancer treatment is one of the most important and vital applications of targeted drug delivery. Conventional chemotherapy agents not only specifically affect cancer cells, but also affect healthy cells and have a destructive effect on them and cause harmful side effects. Therefore, modern drug delivery systems have been considered to overcome these problems. In these systems, the time, place, and rate of drug releasing are well controlled. Therefore, in addition to increase the therapeutic efficacy of the drugs, their side effects are significantly reduced. Also, anti-inflammatory drugs have many side effects, including osteoporosis, which can be reduced by targeted drug delivery (Souto *et al.*, 2010; Barkin, 2015). Each drug delivery system should have the following two characteristics:

- (1) Increasing the effectiveness of the anti-cancer drugs in cancer tissues.
- (2) Reducing the toxicity of the anti-cancer drugs in other healthy tissues.

In general, targeted drug delivery mechanisms are divided into three categories (Torchilin, 2000): physical targeting, active targeting and inactive targeting. In physical targeting, accumulation or dispersion of the drug agents in the desired tissue is done by various external forces such as magnetic field, ultrasound, light, heat and electric field. The magnetic field has been more widely

Fig. 1 Classifications of organic carriers.

used due to its cost effectiveness and ease of operation. Magnetic nanoparticles with unique properties have become attractive drug carriers for targeted drug delivery. Creating bipolar interactions under the influence of an external magnetic field leads to accumulation of the magnetic drug carriers in the target tissue (Xuan *et al.*, 2018; Lu *et al.*, 2012).

Inactive targeting is used when the target tissue has specific physiological characteristics compared to other healthy tissues which can lead to the selective accumulation of the drug in the target tissue. Drug carriers are able to use the structural features of tumor tissue for inactive targeting as follow (Hirsjarvi *et al.*, 2011):

- (1) Enzymatic inactive targeting (conversion of inactive form of drug to active form due to the presence of a specific enzyme).
- (2) Inactive targeting due to environmental acidity difference (drug releasing due to difference in pH of target tissue with other healthy tissues)
- (3) Inactive targeting due to temperature difference (drug releasing due to difference in temperature of target tissue with other healthy tissues)

Inactive targeting can be used effectively to treat cancer tissues, because physiological characteristics of cancer tissues are very different from other healthy tissues due to their high cell division (Gindy and Prud'homme, 2009; Thomas *et al.*, 2013).

Active targeting is the most advanced targeting drug delivery approach. In this method, appropriate ligands such as antibodies are attached to the surface of carriers. The attached ligands on the carriers' surface with binding to a specific antigen on the tumor surface can direct the drug to the target tissue, accurately. A suitable antigen for active targeting should be present on the surface of all cancer cells but not in healthy cells (Salarian *et al.*, 2009; Rapoport *et al.*, 2004; Abou-Jawde *et al.*, 2003; Vogel *et al.*, 2002).

In general, the most important goals of targeted drug delivery are as follow (Kumari *et al.*, 2016):

- (1) Increasing drug concentration in the target tissue (cancer cells) through physical, inactive or active targeting.
- (2) Decreasing drug concentration in normal tissue to avoid harmful side effects.
- (3) Increasing drug stability to reduce drug degradation.
- (4) Releasing maximum drug at the target tissue.
- (5) Improving biocompatibility and biodegradability of drugs.
- (6) Improving internalization and intracellular delivery.

Designing appropriate drug carrier is very important for drug delivery applications (Kumari *et al.*, 2016) The drug carrier should be selected from materials that disappear in the body after a while or do not cause any harmful effects on the body (Vasir and Labhasetwar, 2005). Drug carriers are classified into two groups: organic and inorganic carriers. The most important inorganic carriers are ceramic nanoparticles, metal nanoparticles, magnetic nanoparticles, carbon nanomaterials such as carbon nanotubes (CNTs) and graphene oxide (GO) and etc. Among inorganic carrier, CNTs with unique physical and chemical properties have received considerable attention for drug delivery applications. The classification of organic carriers is shown in Fig. 1. Among organic carrier, hydrogels with unique physical and chemical properties can be used in drug delivery applications, more effectively. Nowadays, polymer matrix composites as a combination of organic and inorganic nanomaterials have received considerable attention for drug delivery applications.

Bibliometric Analysis

The main aspects related to the medical applications of the CNTs-based polymer matrix composites materials can be identified by bibliometric analysis. The number of scholarly studies including books, book articles, journal articles, conference proceeding articles, dissertations, etc., in this research field, over time is illustrated in Fig. 2. As observed, the number of scholarly studies accomplished over the years of 1999–2015 have been significantly increased and then over the years of 2015–2021 decreased. The journal articles have the highest share 89.2%. Fig. 3 shows the top publishers by the number of scholarly works in this field. As can

Fig. 2 Scholarly studies in the field of medical applications of the CNTs-based polymer matrix composites over time. Reprinted from lens.org.

Fig. 3 The top publishers based on the number of accomplished scholarly studies in the field of medical applications of the CNTs-based polymer matrix composites. Reprinted from lens.org.

be observed, Elsevier, American Scientific, Springer nature and Wiley publishers have been published the greatest number of the scholarly works in this research field, respectively. The activity of various countries/regions in this research field based on the number of their scholarly works is shown in Fig. 4. As can be observed, United States of America with 428 scholarly works and China with 423 scholarly works have been the most actively engaged so far. The clusters network visualization of the keywords with the most frequent co-occurrence in this research field is shown in Fig. 5. This chart was obtained by importing the data downloaded from the Scopus into the VOSviewer software (version 1.6.15) and provided valuable information about the scholarly studies conducted so far in this research field. Each circle represents a keyword. The bigger the circle, the bigger the

Fig. 4 The activity of various countries/regions in the field of medical applications of the CNTs-based polymer matrix composites based on the number of scholarly works. Reprinted from lens.org.

occurrence. The co-occurrence relationship between the keywords is presented by curves. Moreover, the distance between two keywords indicates the relationship strength, i.e., the closer the keywords, they are the more related and vice versa. As can be observed in Fig. 5, the keywords are divided into three clusters with different colors:

- (1) Cluster 1 (in green) mainly includes the keywords related to the topic of applications of the CNTs-based polymer matrix composites in drug delivery, such as “drug delivery systems”, “targeted drug delivery”, “metabolism”, “cytotoxicity”, “DNA”, “body fluids”, “biomaterials”, “genetic”, “human”, “nonhuman”, “animals”, “composite materials”, “multi-walled carbon nanotubes”, and “carbon nanotubes”.
- (2) Cluster 2 (in red) mainly includes the keywords related to the topic of applications of the CNTs-based polymer matrix composites in tissue engineering, such as “bone”, “tissue engineering”, “tissue”, “reinforcement”, “composites”, “composite films”, “electrospinning”, “nanofiber”, “mechanical properties”, “biological properties”, “biocompatibility”, “fillers”, “cross-linking” and “single-walled carbon nanotubes”.
- (3) Other clusters mainly include the keywords related to the CNTs-based polymer matrix composites fabrication and their properties, such as “FTIR”, “XRD”, “SEM”, “hardness”, “sintering”, “hydroxyapatite”, “titanium alloys”, “chitosan”, “hydrogels”, “corrosion resistance coating”, “mechanical properties”, “electrophoresis deposition”, “biological materials”, “polymer”, “nanoparticles”, “carbon nanotubes”, “cellulose”, “conducting polymer” and “optical properties”.

These three clusters reveal the major research directions in the field of medical applications of the CNTs-based polymer matrix composites. It is obvious that the CNTs-based polymer matrix composites can be used in drug delivery systems and tissue engineering, effectively.

Carbon Nanotubes: Properties, Functionalization and Drug Delivery Applications

In recent years, carbon nanotubes (CNTs) with unique physical and chemical properties have found many applications in various scientific fields. Recent researches have focused on the application of CNTs in biomedical applications. CNTs with high surface to volume ratio have high loading capacity of drugs and can be used effectively in fabrication of drug delivery systems. CNT based devices can be successfully utilized in stem cell based therapeutic and tissue engineering applications, including bone formation, myocardial therapy, and neuronal and muscle regeneration. Furthermore, CNTs are excellent agents for imaging and biology detection due to their distinct optical properties such as strong Raman shift, high absorption in the near-infrared (NIR) range and photoluminescence properties. CNTs with high surface area for molecular recognition molecules attachment can be used in fabrication of targeted nanodevices for selective sensing and imaging (Shao *et al.*, 2013; Ando, 2010; Simon *et al.*, 2019). Various biomedical applications of CNTs is shown in Fig. 6.

CNTs as cylindrical macromolecules are composed of a hexagonal honeycomb arrangement of carbon atoms with sp^2 hybridization. CNTs can be single-walled (SWCNTs) or multi-walled (MWCNTs) with interlayer distance between walls of 0.34

Fig. 7 Carbon nanotubes: (a) SWCNT and (b) MWCNT.

nm (graphite interlayer distance) as shown in **Fig. 7**. The outer diameter of SWCNTs and MWCNTs is in the ranges of 0.6–2.5 and 2.5–100 nm, respectively. Raw CNTs tend to form nanotube clusters due to attractive van der Waals forces between the tubes. Lack of ability to disperse in water severely limits the use of raw CNTs with hydrophobic nature in biomedical applications. On the other hands, the shelf life of the raw CNTs in biological systems has raised concerns about the use of these materials. Functionalization of CNTs is needed to overcome these limitations (Foldvari and Bagonluri, 2008; Donaldson *et al.*, 2006; Hirsch and Vostrowsky, 2005; Tofighy and Mohammadi, 2019).

CNTs with unique physicochemical properties and high surface to volume ratio and high loading capacity of drugs provide a promising drug delivery system. CNTs with high aspect ratio are more appropriate for drug delivery applications than other types of spherical nanoparticles, because, the hollow and needle-like structure of CNTs allow loading large amounts of drugs in to their hollow structure without affecting their cell penetration capability. CNTs with the adequate loading capacity can carry multi-functional therapeutics, such as drugs, genes and targeting molecules, into one cell to exert multi-valence effects (Bianco *et al.*, 2005; Shao *et al.*, 2013; Simon *et al.*, 2019).

Pharmaceutically active compounds can be loaded onto CNTs in the following three ways (Bianco *et al.*, 2005; Liu *et al.*, 2008):

- (1) Drugs can be encapsulated inside the CNT channel.
- (2) Drugs can be attached to the functional groups on the outer surface of CNTs.
- (3) Drugs can be loaded into the CNTs network as a porous adsorbent.

Hydrophilicity and biological compatibility are important preconditions for nanocarriers used in drug delivery systems. One of the obstacles to the development of CNTs as drug carriers is the hydrophobicity of the graphene side walls of the nanotubes (hydrophobic nature) as well as the strong van der Waals interactions between the nanotubes that cause the nanotubes to accumulate in aqueous solutions. To achieve successful dispersion of the CNTs, the hydrophobic surface of CNTs must be functionalized to reduce bundle formation (Bianco *et al.*, 2005; Shao *et al.*, 2013).

Four effective methods have been proposed to create uniform and stable dispersion of CNTs in aqueous medium (Hirsch and Vostrowsky, 2005; Foldvari and Bagonluri, 2008; Meng *et al.*, 2009):

- (1) Surfactant-assisted dispersion
- (2) Solvent-assisted dispersion
- (3) Biomolecules-assisted dispersion
- (4) Functionalization of the CNTs side walls with various functional groups

Among these methods, functionalization as the most effective method, with the ability to reduce toxicity, improve biocompatibility and create suitable active sites for binding to drug molecules, proteins and genes for the development of drug delivery systems has received much attention Liu *et al.* (2008). CNTs functionalization can be done in two ways: covalently or non-covalently.

Covalent Functionalization

A powerful strategy to introduce numerous functional groups on the CNTs structure is covalent functionalization. Covalent functionalization secures more stable and hydrophilic derivatives than non-covalent functionalization and remarkably facilitates the CNTs dispersion in aqueous solutions and various solvents. Covalent functionalization with altering the carbon atoms hybridization from sp^2 to sp^3 , disrupt the CNTs aromatic character. Oxidation is the most popular form of covalent functionalization which inherently generates oxygen-containing functional groups as polar groups including hydroxyl, carbonyl, carboxyl and epoxy on defect sites and both tips of CNTs which improve dispersion ability of CNTs, significantly. In the oxidation method, drastic reaction conditions, such as CNTs refluxing in strong acids such as HNO_3/H_2SO_4 , HNO_3 , $KMnO_4/H_2SO_4$ and etc. are needed. The oxidation reactions cause structural defects over the tubular structure of CNTs and therefore damage the CNTs structural integrity. Also, loss of small diameter CNTs and even loss of the entire material as well as shortening of the tubes length, are another drawbacks of the oxidation method. Carboxylic acids groups permit further incorporation of other functional groups

on the CNTs structure. However, at first, pre-activation of these functional groups either by coupling agents such as carbodiimides and hydroxybenzotriazole or by acyl chlorides such as thionyl chloride or oxalyl chloride is necessary (Shao *et al.*, 2013; Meng *et al.*, 2009; Tofghy and Mohammadi, 2019; Hu *et al.*, 2003; Karousis *et al.*, 2010; Georgakilas *et al.*, 2002).

Non-Covalent Functionalization

Non-covalent functionalization methods are conventionally carried out under simple reaction conditions such as sonication and centrifuge, and obviate the necessity of harsh reactions conditions and strong reagents and appear to be more favorable than covalent functionalization methods. In addition, non-covalent functionalization methods do not damage the CNTs aromatic structure as well as the structural integrity of both graphitic tips and surface. The main drawbacks of the non-covalent functionalized CNTs are low durability of the non-covalent conjugates which may even undergo exchange with serum proteins or may dissociate from CNTs in biological fluids. This undesirable performance may cause toxicity and some other harmful outcomes undoubtedly.

Non-covalent functionalization can be performed by polymers, surfactants, and biological materials including nucleic acids, proteins, and peptides incorporation on the outer walls of CNTs by simple physical adsorption through van der Waals forces, π - π interactions and etc. As reported in the literature, it appears that the molecules containing aromatic groups (for example sodium dodecyl benzene sulfonate (SDBS) or biopolymers including peptides and single-stranded nucleic acids containing aromatic acids) can better improve dispersion ability of CNTs as a result of better π - π interactions. It should be mentioned that these materials are bonded on the outer walls of CNTs in divergent geometries for example surfactants form micelle-like assemblies around CNTs and polymeric materials wrap around CNTs to maximize van der Waals interactions (Shao *et al.*, 2013; Tofghy and Mohammadi, 2019; Kim *et al.*, 2012; Tasis *et al.*, 2003).

Polymeric Hydrogels

Polymeric hydrogels as promising bio-materials have received considerable attention. Hydrogels are composed of crosslinked hydrophilic polymer networks that are insoluble in water and can hold large amounts of biological fluids in the space between their polymer chains. The water holding capacity of hydrogels depends on the amount of hydrophilic functional groups including hydroxyl, carboxyl, amido and amino groups, etc. in the polymer chains. The hydrogels water content can be from 10% to thousands times of the dry polymer network weight. In addition, hydrogels with excellent biocompatibility can be employed in medical applications including artificial organs, tissue engineering, contact lenses, wound dressings, prostheses, and drug delivery systems (Singh and Pal, 2008; Sorbara *et al.*, 2009; Wu *et al.*, 2007).

Hydrogels can be natural or synthetic, based on their origins. The natural origins of hydrogels include chitosan and chitin, (Bobokalonov *et al.*, 2012) dextran, (Cirillo *et al.*, 2014) alginic acid, (Li *et al.*, 2012) agarose, (Zhang *et al.*, 2012) pectin, (Della Rocca *et al.*, 2012) and different derivatives of these polymers and the synthetic origins of hydrogels are included polyvinyl alcohol (PVA), (Zhang *et al.*, 2012) polyethylene glycol (PEG), (Kost and Langer, 2012) polyacrylamide (PAM), (Zhu *et al.*, 2012) polyacrylic acid (PAA) (He *et al.*, 2008) and polymethyl methacrylate (PMA) (Samanta *et al.*, 2012).

Hydrogels are classified into permanent and non-permanent hydrogels based on the nature of their crosslinking. In permanent (chemical) hydrogels, covalent bonds are formed between the polymer chains during the crosslinking reaction (for example hydrogels based on acrylic monomers). In non-permanent (physical) hydrogels, the polymer chains are crosslinked by formation of physical interactions including ionic, van der Waals and hydrogen interactions and molecular entanglement (for example agar-agar and gelatin hydrogels) (Cirillo *et al.*, 2014; Hoffman, 2012).

Some hydrogels that are able to respond to external stimuli by changing phase or changing equilibrium are referred to as "smart" or "stimuli-responsive" hydrogels. Smart hydrogels have been used in targeted drug delivery due to their ability to respond to the environmental parameters such as biochemical, chemical and physical stimuli. The most important physical stimuli are pressure, temperature, sound, light, and magnetic and electric fields, while chemical stimuli include pH, ions, ionic strength and so on (Kim *et al.*, 2003; Li *et al.*, 2004).

Basis on the external stimuli type, smart hydrogels are divided into heat-sensitive hydrogels, pH-sensitive hydrogels, light-sensitive hydrogels, electro-sensitive hydrogels and so on. External stimuli can be applied to hydrogels in a variety of ways, such as the use of potassium phosphate buffer for pH-sensitive hydrogels, the use of IR irradiation and/or hot plates for heat-sensitive hydrogels, the use of voltage by appropriate inert electrodes for electro-sensitive hydrogels and so on (Yun *et al.*, 2010).

Hydrogels with high water content and soft and elastomeric nature resemble living tissues which minimizing frictional and mechanical irritation. Hydrogels with low interfacial tension exhibit minimal tendency to proteins absorption from body fluids and cell adhesion. Furthermore, the swelling capacity of hydrogels causes the removal of reagent residues to be easy. The biggest disadvantage of hydrogels is their high water content which causes their poor mechanical properties. The mechanical properties of hydrogels can be improved through chemical crosslinking (preparation of interpenetrating polymer networks (IPN)). However, the disadvantage of chemical crosslinking method is the presence of residual crosslinking agents resulting in some toxic side effects. Other limitations of hydrogels using as drug delivery systems are burst or incomplete therapeutic agent release as well as poor scalability of their manufacturing processes (Cirillo *et al.*, 2011; Altimari *et al.*, 2012; Li *et al.*, 2003). In order to overcome

these drawbacks, hydrogel composites materials as a combination of nanomaterials and polymeric chains have been recently developed.

Hydrogel Composites

To enhance drug release profile, mechanical strength, biological interactions and remote actuation capabilities of hydrogels, hydrogel composites have been developed by incorporation of nanomaterials into hydrogel matrices for biomedical and pharmaceutical applications. Hydrogel composites containing different nanomaterials, including gold, clay, silver, CNTs, iron oxide, tricalcium phosphate and hydroxyapatite as fillers have been developed as biomaterials (Satarkar *et al.*, 2010; Lovinger, 2005). Among these composites, CNTs-based hydrogel composites with unique physicochemical properties have received considerable attention for drug delivery applications.

CNTs-based hydrogel composites

The first CNTs-based polymer nanocomposite was reported in 1994 by DeHeer *et al.* (1995). Nowadays, CNTs have been recognized as appropriate nanofiller to improve the physicochemical properties of polymers. As reported in the literature, the CNTs-based hydrogel composites can be used effectively in many fields including semiconductor device manufacturing, nanobiotechnology, molecular recognition, nanofluidics, catalysis, drug delivery and molecule specific chemobiosensing. Therefore, finding new effective methods to fabricate the CNTs-based hydrogels have received considerable attention. As reported in the literature, the covalent and non-covalent functionalization of CNTs with polymeric materials are the main adopted synthesis approach of the CNTs-based hydrogel composites. As mentioned in the previous section, in the non-covalent functionalization method, the intrinsic properties of CNTs don't change, however, in the covalent functionalization method, with changing hybridization of carbon atoms from sp^2 to sp^3 , abundant functional groups are formed on the CNTs sidewall structure. In the covalent functionalization, the CNTs sidewalls with sp^2 hybridization contain highly delocalized π electrons which bond with π electron rich compounds through π - π interactions. This organic functionalization method avoids changing the CNTs intrinsic structures and the structurally intact functionalized CNTs are fabricated (Wang *et al.*, 2004). The CNTs-based polymeric composites fabrication through the covalent functionalization method consists of "grafting from" and "grafting to" methods (Liu *et al.*, 2004; Baskaran *et al.*, 2004). In the "grafting from" method, monomers are polymerized on the surface of CNTs from surface-derived initiators, while the "grafting to" method involves the polymeric chains reaction with the either raw or pre-functionalized CNTs. Low grafting density is the main limitation of the "grafting to" technique due to initial binding of polymer chains sterically that hinders diffusion of additional macromolecules to the surface of CNTs. The "grafting from" approach causes to obtain efficiently grafted polymers with high molecular weight on the CNTs surface, because polymer growth is not limited by the steric hindrance. Therefore, functionalized CNTs with high polymer grafting density can be fabricated through the "grafting from" approach (Yan and Yang, 2009; Mylvaganam and Zhang, 2004). Many techniques including "click" chemistry, (Li *et al.*, 2005) esterification, (Gao *et al.*, 2007) pyrene moiety adsorption, (Martin *et al.*, 2004) layer-by-layer self-assembly, (Kong *et al.*, 2005) radical coupling, (Cirillo *et al.*, 2013) anionic coupling, (Huang *et al.*, 2004) supercritical CO_2 -solubilized polymerization or coating, (Dai *et al.*, 2004) radical polymerization, (Qin *et al.*, 2004) γ -ray irradiation, (Xu *et al.*, 2006) polycondensation, (Zeng *et al.*, 2006) cathodic electrochemical grafting, (Petrov *et al.*, 2004) reversible addition fragmentation chain-transfer (RAFT) polymerization, (Xu *et al.*, 2006) ring-opening polymerization (Qu *et al.*, 2005) and anionic polymerization (Chen *et al.*, 2006) have been used for fabrication of the CNTs-based polymeric composites.

Conclusions

Cancer is one of the leading causes of death worldwide. Today, nanotechnology has revolutionized the cancer treatment by improving current cancer treatment methods as well as making new drug and drug carriers. CNTs as a one-dimensional nanomaterial with unique physicochemical properties including high drug-loading, excellent penetrating capability in the cellular barriers, easy modification with other molecules, large surface area, excellent electronic, magnetic and thermal properties, and good pH-dependent unloading capacity can be employed as an efficient and promising delivery system of many therapeutic active compounds, ranging from cardiovascular drugs, antineoplastic agents, anti-inflammatory, anti-infective and anti-cancer drugs, and genes. Polymeric hydrogels as promising bio-materials have also received considerable attention for drug delivery applications. But the main limitations of the hydrogels as drug delivery systems are burst or incomplete therapeutic agent release as well as poor scalability of their manufacturing processes. In order to overcome these drawbacks, hydrogel composites materials as a combination of nanomaterials and polymeric chains have been recently developed. CNTs-based hydrogels with improved mechanical, physicochemical, and biological properties than hydrogels can be considered as appropriate drug delivery systems.

Introduction

Biopolymers are achieved from living organisms so that they are produced by plants and microbial organisms or synthesized using biological materials (Shariatinia 2019a,b; George *et al.*, 2020; Shuai *et al.*, 2020). They exhibit several benefits relative to the synthetic polymers especially due to their high biodegradability, biocompatibility and non-toxicity (Fazli *et al.*, 2016; Fazli and Shariatinia, 2017; Kabir *et al.*, 2020; Vinod *et al.*, 2020). Biopolymers are frequently employed in biomedical areas as clothing fabrics, packaging, food additives, water treatment materials, biosensors, cosmetics, absorbents, data storage compounds and industrial plastics (Kohsari *et al.*, 2016a,b; Mazloom-Jalali and Shariatinia, 2019; Negm *et al.*, 2020; Stanisz *et al.*, 2020). Biopolymers can be classified in three groups including polynucleotides, proteins and polysaccharides (Shariatinia and Fazli, 2015; Shariatinia and Barzegari, 2019; Shariatinia and Fasihozaman-Langroodi, 2019; Varaprasad *et al.*, 2020). Most biopolymers create non-immunogenic degradation products; thus, they are utilized in therapeutic purposes like porous three-dimensional scaffolds in tissue engineering, temporary prostheses, adhesion/fixation/suturing biomaterials, three-dimensional bio-printing, wound healing and sustained/controlled drug carriers (Park *et al.*, 2017; Shariatinia and Jalali, 2018; Shariatinia and Mohammadi-Denyani, 2018; Shariatinia and Mazloom-Jalali, 2019).

Recently, the biopolymer composites, principally those resulting from polysaccharides and proteins, have become highly attracting materials for application in medical fields (Rai *et al.*, 2015; Mazloom-Jalali *et al.*, 2020). These usage materials are extremely biocompatible, naturally and easily available, abundant, biodegradable, non-carcinogenic, non-mutagenic, non-immunogenic, non-irritating, edible, and reveal appropriate mechanical and hemo-compatibility features and capable of adsorbing/encapsulating bioactive agents (Shariatinia and Nikfar, 2013; Shariatinia *et al.*, 2015; Wsoo *et al.*, 2020). Also, they have biomimetic functions that are analogous to the native extracellular matrix, ECM, in human beings and other living organisms (Kazemi *et al.*, 2016; Shariatinia and Zahraee, 2017; Wei *et al.*, 2019). Biopolymer composite materials can be fabricated by mixing the biopolymer solution/melt with nano/micro-materials to exploit the advantageous characteristics of all constituents (Kim *et al.*, 2019; Shariatinia 2019a,b).

The mechanical features of biopolymer composites such as tensile and impact strengths can be greatly improved through adding inorganic, organic and hybrid nano/micro-materials into the polymer (Ong *et al.*, 2019). It is noteworthy that the biopolymer properties (such as chemical formula, molecular weight, processing method and morphology) in the composites can also greatly affect their mechanical characteristics (Shariatinia and Jalali, 2018; Shariatinia, 2019a,b). The physicochemical characteristics of biopolymer composites like solubility, morphology, structure, chemical functionalization/modification by appropriate substances, ECM biomimicry and tensile strength control their mechanical features and allow preparing them as diverse shapes for different applications including tubes, films, scaffolds, electrospun fibers, sponges, porous sponges, microbeads, dressing materials, sheets, membranes, hydrogels and microcapsules (Rousselle *et al.*, 2019).

Usually, biopolymer composites reveal higher levels of antibacterial activities compared to those of their related pure biopolymers and this is associated with the presence of nano/micro-materials within their matrixes (Fazli *et al.*, 2016; Fazli and Shariatinia, 2017). Accordingly, the biopolymer composites have been applied in numerous industries ranging from blends and additives within bioplastics to edible goods, personal hygiene, medical products, cancer/tumor treatment, wound healing, radiotherapy, tissue engineering, imaging and diagnosis, fabrication of implants, as well as delivery systems for drugs, nucleic acids, genes, peptides, proteins and vaccines (Ling *et al.*, 2018).

The most significant inorganic materials used in drug delivery include Au, Ag, TiO₂, ZnO, clay and SiO₂ nano-/micro-particles, zeolites, diatomites, graphene, carbon quantum dots, carbon nanotubes, hydroxyapatite and bioglass (Shariatinia *et al.*, 2011a,b, 2012; Shariatinia and Shahidi, 2014; Nikfar and Shariatinia, 2017a,b, 2019). Additionally, these materials can be introduced to the biopolymer matrixes as fillers in the forms of micro-/nano-particles, core-shell, yolk-shell and composites (Vatanparast and Shariatinia, 2018a,b; Kassem *et al.*, 2019; Vatanparast and Shariatinia, 2019a,b). A large number of biopolymers have been utilized to fabricate bio-composites such as chitosan, carboxymethyl chitosan, alginate, cellulose, carboxymethyl cellulose, hydroxyethylcellulose, starch, hyaluronic acid, gellan gum, acacia gum, guar gum, gelatin, chondroitin sulfated pectin and collagen (Khan and Mujahid, 2019; Yuan *et al.*, 2019; Vasvani *et al.*, 2020).

Medical Applications of Chitosan, Carboxymethyl Chitosan, Alginate and Hyaluronic Acid Composites

Chitosan (CS), carboxymethyl chitosan (CMCS), alginate and hyaluronic acid (HA) as well as their composites are well-known biopolymeric materials that are widely employed in various medical applications. Several examples are given in the following to indicate the most recent applications of these biologically important substances.

Micro-composites (with $0.151 \pm 0.49 \mu\text{m}$ mean size and spherical morphology) of CS and halloysite nanotubes were synthesized as mucoadhesive drug carriers (Sharif *et al.*, 2019). Micro-composites revealed adhesion onto the intestinal mucosa, the highest swelling value at acidic pH and released metoclopramide hydrochloride drug in a sustained manner (66.8% at

Fig. 1 SEM images of RBCs (a1–a3) and platelets (a4–a6) adhesion on composite dressing at different magnification after incubation of 30 min (a), photographs of tube containing fresh blood without any composite dressing (b), blood clotted with the dressing incubated for 5 min (1), 10 min (2) and 15 min (3) (c), and RBCs leaked from composite dressing for time period of 5 min, 10 min and 15 min (d). (Data points: mean $\pm$ SD and $n = 3$). Reprinted with permission from Biranje, S.S., Madiwale, P.V., Patankar, K.C., *et al.*, 2020. Cytotoxicity and hemostatic activity of chitosan/carrageenan composite wound healing dressing for traumatic hemorrhage. In: Kennedy, J.F., Coimbra, M. (Eds.), *Carbohydrate Polymers*, vol. 239. Elsevier, 116106.

pH = 1.2 but 46.7% at pH = 5.5 in 25 h). The micro-composites containing the greatest CS amount exhibited the most adhered onto the intestinal mucosa after 3 h ($89 \pm 1.79\%$). Some dental restorative composite resins were developed using CS and CS loaded by anhydrous calcium phosphate particles (0, 0.5, 1.0 wt%) indicating antimicrobial activities against *Streptococcus mutans* without losing their biocompatibility and mechanical characteristics (Tanaka *et al.*, 2020). Composite scaffolds of CS and chondroitin sulfate (CTS) containing bioglass nanoparticles were prepared using polyelectrolyte complexation method for application in bone tissue engineering (Singh *et al.*, 2019). The *in vitro* cellular cytotoxicity, viability, spreading and adhesion were assessed in order to estimate the scaffolds effects. Also, the expression of collagen type I, biomineralization and alkaline phosphatase activity were considerably greater on the composite CS scaffold demonstrating its enhanced osteogenic capacity. Moreover, the *in vivo* iliac crest bone defect investigation proved that the implanted composite scaffold facilitated integration with the native bone tissue and assisted the tissue regeneration. A biocompatible composite of CS and carrageenan was achieved as wound dressing to be used in healing of traumatic hemorrhage (see Fig. 1; Biranje *et al.*, 2020). A composite of CS and doxorubicin was electrochemically deposited onto the Ti alloy coated by the hydroxyapatite to decrease the side effects of sustained drug release localized nearby the tumor tissue with the aim of cancer inhibition/apoptosis (Lai *et al.*, 2019). A multifunctional composite food packaging coating indicating biodegradable, transparent, antibacterial and antifogging features was produced using CS modified with a quaternary ammonium salt and poly(vinyl alcohol) by the simple environmentally benign solution casting process (Min *et al.*, 2020). A multifunctional nanocomposite was achieved using hybrid gold/iron oxide nanoparticles that were conjugated to the methotrexate and coated by oleyl CS for application as a dual acting material in the magnetic resonance imaging, MRI, and computed tomography, CT (Hemalatha *et al.*, 2018). Some hydrogels were developed based on the CS, carboxymethyl cellulose (CMC) and hydroxyapatite loaded by different amounts of thyroxine (0.1, 0.5 and 1 $\mu\text{g/mL}$) to improve the angiogenesis in the *in vivo* assays (Malik *et al.*, 2020). The angiogenic activities of the hydrogels were established using the chick chorioallantoic membrane test and it was shown that the hydrogel composed of 0.1 $\mu\text{g/mL}$ thyroxine had the highest neovascularization. Also, the

cytotoxicity test using MC3T3-E1 preosteoblast cells seeded onto the hydrogels confirmed that these materials with the pro-angiogenic capacity were not toxic and suitable for the periodontal regeneration.

It is known that the Gd/Mn containing small molecules used as the MRI contrast agents are not very stable during the extended monitoring and safe if high and repeating doses of them are administered. Hence, a macromolecular biocompatible MRI contrast agent was synthesized using O-CMCS and CMCS-(Mn-DTPA)_n (Wang *et al.*, 2019a). It was found that the CMCS-(Mn-DTPA)_n had a relaxation time that was nearly 5.5 and 3.5 times greater compared to those of the Mn-DPDP and Gd-DTPA within the aqueous environment, respectively (Fig. 2). The intensity of the MRI signals were highly enhanced within the liver and kidney of Sprague Dawley rats using 0.03 mM of Mn/kg b.w. (Fig. 3). The *in vivo* tests approved that Mn was fully excreted from the Sprague Dawley rats in ten days post administration so that it did not exert any pathological effects on their livers. Nanoparticles of core-shell metal organic framework/carbon dots@O-CMCS, were obtained for application in the *in vitro* dual mode imaging, diagnosis, pH-responsive drug delivery and cancer therapy (Lin *et al.*, 2020). The O-CMCS hydrogel conjugated by caffeic acid in addition to its composite with polyacrylamide were developed by means of electron beam irradiation and utilized as antibacterial wound dressings that could deliver doxycycline antibiotic drug (Hafezi Moghaddam *et al.*, 2020). Composite hydrogels of CMCS comprised of hydroxylated lecithin-iodine, HLI, complexes and sodium alginate were prepared using microwave drying method and used in treatment of the infected burn wounds which displayed extraordinary repairing efficacies on the seawater immersed infected wound in rats with deep partially thick burns, see Figs. 4 and 5 (Chen *et al.*, 2019).

The biological, antibacterial and mechanical characteristics of alginate composite scaffolds were improved through incorporation of magnesium and bioactive zinc containing bioglass that illustrated bactericidal activities (Fig. 6) and were effectively utilized in bone tissue engineering using MG-63 cells (Fig. 7; Zamani *et al.*, 2019). A magnetic bio-inspired hydrogel was fabricated using alginate, gelatin and magnetic Fe₃O₄ nanoparticles, which was employed as a smart and effective drug carrier in cancer treatment against HeLa cells (Jahanban-Esfahlan *et al.*, 2020). A pH-sensitive drug delivery vehicle was fabricated using graphene oxide modified with protamine sulfate as a natural peptide and sodium alginate using the layer-by-layer self-assembly for the delivery of anticancer drug, doxorubicin hydrochloride (Xie *et al.*, 2018). The osteogenic capacity of a composite prepared using poly(vinyl pyrrolidone) and silicate and lanthanum (SiO₄⁴⁻ and La³⁺) substituted hydroxyapatite (synthesized using the calcium alginate as the template) was tested by coating the composite on the surface of a titanium, Ti, implant (Barros *et al.*, 2020).

The effectiveness of HA and poly-D,L lactic acid was explored on the fixation of implants coated the granules of beta-tri-calcium phosphate/hydroxyapatite by a clinical *in vivo* test on sheep which indicated formation of the fresh bones in all groups (Andreassen *et al.*, 2017). The hydrophobic and unstable D- α -tocopherol succinate, α -TOS, was encapsulated inside the pores of zeolitic imidazolate framework-8, ZIF-8, called α -TOS@ZIF-8, and then coated by the HA shell to achieve the HA/ α -TOS@ZIF-8 nanomaterial which was used for the antitumor treatments against human cervical carcinoma, HeLa, cells *in vitro* and U14 uterine cervical tumor bearing mice *in vivo*, see Figs. 8–10 (Sun *et al.*, 2019a). CS/HA sponge composite scaffolds containing andrographolide lipid nanocarriers were fabricated as wound dressing materials which exhibited wound healing in rats without leaving scars (Sanad and Abdel-Bar, 2017). Recently, an electrodeposition layer of Ce(NO₃)₃ · 6H₂O was formed onto the magnesium, and HA was coated by the hydrothermal method to form a polymeric composite layer containing cerium materials plus a stable thick layer of MgO (Kim *et al.*, 2020). Application of this composite on the osteoblasts illustrated their cell viability and non-toxicity to Ce and maximum differentiation particularly using the hydrothermally coated HA. Furthermore, implantation in rat tibias revealed the constant growth of osteoblast and bone marrow using the hydrothermally coated HA. Therefore, CeO₂ and Ce(OH)₃ penetrated into the HA polymer and caused a self-healing capacity, primary corrosion resistance, biodegradation and localized damage of the magnesium implant.

Medical Applications of Cellulose, Carboxymethyl Cellulose, Hydroxyethyl Cellulose and Chondroitin Sulfate Composites

Cellulose, carboxymethyl cellulose (CMC), hydroxyethyl cellulose (HEC) and chondroitin sulfate (CTS) are biopolymers with outstanding properties such as nontoxicity, sustainability, biocompatibility, biodegradability, low cost and hydrophilicity that make them appropriate materials for biomedical applications.

Nanocomposite of cellulose nanocrystals and ultra-small Fe₃O₄ superparamagnetic nanoparticles could be used as a dual negative and positive T₁ and T₂ MRI contrast agent with large saturation magnetization of 52.2 emu/g, high relaxation parameters (r₁ and r₂ were 13.8 and 96.2 mM⁻¹ s⁻¹) plus suitable r₂/r₁ of 7.0 at 3.0 T (Torkashvand and Sarlak, 2019). The nanocomposite displayed satisfactorily *in vitro* cell uptake, *in vitro* low toxicity (200 μ g/mL Fe) against HeLa cells, exceptional biocompatibility and colloidal durability confirming it was a favorable material for application in the medical areas. Some electrospun heparin-like nanofibrous membranes were fabricated using CMCS and bacterial cellulose sulfate demonstrating thrombin, prothrombin and activated partial thrombin times of 48.4, 16.2 and 67.4, respectively, that were 50%, 189.8% and 116.0% greater compared to those of the plasma (Song *et al.*, 2018). Bacterial cellulose/CS scaffolds were attained to be employed in ovarian cancer diagnosis through the interaction of scaffolds with the A2780 ovarian cancer cells (Ul-Islam *et al.*, 2019). A biodegradable composite gauze was prepared by means of N, O-CMCS and oxidized regenerated cellulose that was utilized as a wound dressing barrier to prevent the postoperative adhesion and illustrated antibacterial activities against *E. coli* and *S. aureus* microorganisms (Cheng *et al.*, 2019). Bacterial cellulose scaffolds modified with alginate and incorporated with different amounts of doxorubicin drug were achieved for the local release of doxorubicin in HT-29 human colorectal cells that displayed 53%–95% loss in viability of cells after 24 h and

37%–63% after 48 h (Cacicedo *et al.*, 2016). The core-shell nanoparticles were fabricated using Fe₃O₄ core coated by the hydrogel shell that was dually encapsulated with both hematoporphyrin monomethyl ether and doxorubicin and then conjugated with the folic acid which was grafted to the composite surface and introduced in the bacterial cellulose membrane (Zhang *et al.*, 2019). On the day 14 post treatment, the tumor growth inhibition was 80.38%. The transdermal delivery of the composite to the breast cancer cells was done by applying laser and a magnetic field and low penetration depth was happened which enhanced the transdermal delivery of drugs and facilitated the bypass by the stratum corneum barrier.

Composite microbeads of Fe₃O₄@C/CMC/CS were we produced as a dual magnetic and pH responsive formulation and used in controlled delivery of diclofenac sodium to the gastrointestinal tract without burst release (Sun *et al.*, 2019b). Several hydrogel composite films were fabricated using CS microspheres incorporated to the CMC hydrogel as redox responsive systems through cystamine dihydrochloride as a disulfide crosslinker and employed for the co-delivery of 5-fluorouracil anticancer and tetracycline hydrochloride antibiotic drugs (Wang *et al.*, 2019b). A CMC-CMCS-collagen (COL) composite was achieved through crosslinking catalyzed by transglutaminase that was utilized as an anti-adhesion membrane composed of different ratios of CMC, CMCS and COL including 25/25/50, 35/35/30 and 40/40/20 (Figs. 11 and 12; Cai *et al.*, 2018). Porous CS/CMC scaffolds were prepared through freeze drying technique that were reinforced using whisker shaped triphasic and biphasic calcium phosphate fibers and used in bone tissue engineering (Matinfar *et al.*, 2019).

Some composite scaffolds of HEC, sodium alginate and hydroxyapatite were fabricated by crosslinking with the calcium ions the lyophilization process to enhance the *in vitro* regeneration of bone tissue and it was found that they led to proliferation and viability of cell human mesenchymal stem cells *in vitro* (Tohamy *et al.*, 2018). Composite scaffolds of HEC/Ag nanoparticles were produced for the application in skin tissue engineering using hFB human fibroblast cells and it was illustrated that the scaffolds had low toxicity *in vitro* to the cells (Zulkifli *et al.*, 2017). a biocompatible porous scaffold was to developed based on HEC and poly(vinyl alcohol) by the freeze drying procedure which demonstrated enhanced adhesion to the hFB human fibroblast cells and good cell proliferation 7 days post cultivation (Zulkifli *et al.*, 2019). Composite sponges were made using HEC and soy protein isolate that were crosslinked by ethylene glycol diglycidyl ether through the freeze drying technique and revealed satisfactory biocompatibility and adhesion of L929 murine fibroblast cells onto nearly everywhere of their interiors and surfaces confirming they were suitable materials for the tissue engineering (Zhao *et al.*, 2018).

A microporous blend membrane was fabricated as directed bone regeneration based upon the strontium CTS and silk fibroin, called SrCTS/SF, and it was displayed that its water retention capability and mechanical characteristics as well as proliferation of the osteoblasts were improved by increasing the SrCTS content (Fenbo *et al.*, 2019). A biodegradable self-crosslinked and *in situ*

formed injectable hydrogel was synthesized using CTS conjugated to adipic dihydrazide, CTS-ADH, and oxidized pullulan, oxPL which was employed in cartilage tissue engineering (Li *et al.*, 2018). It was recognized that the rabbit articular chondrocytes were encapsulated within the CTS-ADH/oxPL hydrogels 14 days post culturing so that the hydrogel was well cytocompatible according to the live/dead staining test and favored deposition of the cartilaginous extracellular matrix as proved by the amount of sulfated glycosaminoglycan. A composite hydrogel resembling cell delivery system was achieved using type II collagen and CTS crosslinked by genipin that was used to deliver the adipose-derived stem cells (Zhou *et al.*, 2018). The biocompatible scaffold induced the *in vitro* differentiation of cells, regenerated *in vivo* the rat coccygeal vertebrae degenerated model by promoting the expression of genes specific to nucleus pulposus. Nanoparticles of CTS A/deoxycholic acid were conjugated to the polyethylene glycol and used in the tumor targeted doxorubicin delivery to the ovarian cancer (Lee *et al.*, 2016). The conjugated nanoparticles revealed endocytosis into the SKOV-3 cells that were CD44 receptor-positive human ovarian cancer cells. A polyelectrolyte complex was prepared based on CTS and CS which formed an *in situ* scaffold that was not hemolytic, suitably blood compatible and exhibited small blood clotting index with satisfactory antibacterial capacity against Gram-negative and Gram-positive microorganisms, appropriate cytocompatibility as well as almost four times enhanced density of L929 fibroblast cells than that of the control confirming it could effectively control the chronic wounds (Sharma *et al.*, 2019).

Medical Applications of Starch, Carboxymethyl Starch, Zein and Gelatin Composites

Starch, carboxymethyl starch (CMS), zein and gelatin (GEL) are famous biopolymers that are frequently applied in various biomedical purposes. Herein, some recent examples are provided to indicate their significance.

Porous composites of starch-HA were fabricated by crosslinking with sodium trimetaphosphate and utilized as hemostatic materials which displayed exceptional blood clotting in superficial injuries, artery trauma and solid viscera and demonstrated a hemostatic efficiency comparable to that of the commercial Quickclean® hemostat particles (Wang *et al.*, 2020). Some hybrid composite gels were generated through the vacuum freeze drying method using a high amylose starch and microcrystalline cellulose that encapsulated the ranitidine hydrochloride drug and used for the gastric floating delivery (Xu *et al.*, 2019). The *in vitro* drug release test indicated that the 3:7 wt/wt% of starch: cellulose gel revealed 45.87% release in the initial 1 h and a then a sustained drug release in 10 h within simulated gastric fluid. A hydrogel micro-composite was prepared based on starch and cellulose nanowhiskers by the ultrasound irradiation and loaded by the vitamin B₁₂ which exhibited a sustained drug release (Mauricio *et al.*, 2015). Starch conjugated graphene nanosheets were obtained as pH sensitive nano-carriers by reducing exfoliated graphene oxide with soluble starch that was served as a functionalization and reducing agent that capped the graphene nanosheets and prevented their aggregation (Liu *et al.*, 2015). The hydroxycamptothecin drug loaded nano-carriers illustrated no cellular to

SW-620 cells even using 200 g/mL concentration. Also, they were internalized into the SW-620 cancer cells *via* the non-specific endocytosis influence. At acidic pH and in presence of the diastase enzymes existing within the SW-620 cells, the composite nanocarriers were highly toxic towards the SW-620 cells and depicted a pH responsive and *in vitro* starch assisted sustained release that resulted in improved therapeutic efficiency.

CMS coated superparamagnetic Fe_3O_4 nanoparticles were fabricated for the MRI imaging and also for the controlled delivery of the 5-aminosalicylic acid, mesalamine, drug parenterally administered (Saboktakin *et al.*, 2009). CS and its CMS polyelectrolyte complexes were fabricated as tablets achieved through direct compression method using two diverse grades of CS and different CS: CMS ratios which contained the acetaminophen drug (Leonida *et al.*, 2018). It was found that previous incubation of the tablets into the acidic simulated gastric fluid produced longer dissolution plots with complete drug release during 16 h and maintaining the shapes of tablets but tablets directly exposed into the simulated intestinal fluid were quickly degraded. Nanocomposites of CMS (from Assam Bora rice) coated superparamagnetic Fe_3O_4 nanoparticles were synthesized and localized *in vitro* inside micro capillaries to simulate targeted drug vehicles responding to the applied external magnetic field (Mohapatra *et al.*, 2018).

Fig. 10 Hematoxylin and eosin (H&E) and terminal deoxynucleotidyl transferase mediated dUTP-biotin nick end labeling assay (TUNEL) images of tumor tissues from mice after different treatments on the 14th day (scale bar: H&E 56 μm , TUNEL 50 μm). Reprinted with permission from Sun, Q., Bi, H., Wang, Z., *et al.*, 2019a. Hyaluronic acid-targeted and pH-responsive drug delivery system based on metal-organic frameworks for efficient antitumor therapy. *Biomaterials* 223, 119473.

A biodegradable, biocompatible and hemostatic formulation was produced through modification of CMS by calcium ions to achieve freely flowing micro-particles indicating enhanced clotting effects approved by the *in vivo* and *in vitro* assays (Figs. 13 and 14; Panwar *et al.*, 2019). Microparticles of CMS/CS polyelectrolyte complexes were achieved as drug carriers encapsulated the bovine serum albumin that exhibited pH sensitive *in vitro* drug release in both of the simulated intestinal fluid and simulated gastric fluid with pH values of 6.8 and 1.2, respectively (Quadrado and Fajardo, 2020).

Nanofibrous electrospun zein mats (diameters of ~ 350 – 500 nm) incorporated with the Ag nanoparticles (~ 20 nm) were concurrently were fabricated as wound dressing materials and revealed high bactericidal activities against Gram-negative *E. coli* and Gram-positive *S. aureus* bacteria (Dashdorj *et al.*, 2015). Several electrospun fibrous and antibacterial scaffolds were achieved by three different electrospinning approaches (suspension, multilayer and two-nozzle electrospinning) based on poly(ϵ -caprolactone), zein and gum arabic encapsulated with *Calendula officinalis* extract that is a significant therapeutic plant generally utilized to treat skin injuries like cuts, burns, rashes, foot ulcer and bruise (Pedram Rad *et al.*, 2019). It was shown that the scaffolds containing *Calendula officinalis* extract exhibited greater bactericidal capacities than those fabricated without adding the extract confirming they were appropriate for the skin tissue engineering. electrospun nanofiber mats were produced by zein and cellulose acetate and loaded with sesamol antioxidant to assist the wound healing process to examine the influences of sesamol incorporated nanofibrous composite mats onto the wound healing in diabetic mice (Liu *et al.*, 2020). It was indicated that the nanocomposite mat contained a high dose of 5% sesamol relative to the total polymer weight, could induce the myofibroblasts creation through enhancement of the TGF- β signaling path transduction. Also, it stimulated the growth of keratinocytes through inhibition of the chronic inflammation within the wounds and led to improved healing of wounds in diabetic mice. Some macroporous composite scaffolds were prepared as anti-infective, antibacterial, biodegradable and osteo-inductive materials to enhance the bone tissue regeneration using SBA-15 nanoparticles, zein and hydroxypropyltrimethyl ammonium chloride CS, HACC, that were encapsulated by rhBMP-2 to deliver osteogenic factors and expedite efficient repairing the bone defects, see Fig. 15 (Zhou *et al.*, 2014). Zein/HA nanoparticles were obtained using sodium hyaluronate (100 kDa) to deliver the anticancer drug curcumin (loading capacity and encapsulation efficiency were 3.66% and 95.03%, respectively) that displayed a high resistance to the photodegradation and controlled drug release within the simulated gastrointestinal fluid (Chen *et al.*, 2018).

Antibacterial and hemo-compatible wound dressings were achieved based on the composite hydrogels prepared from konjac glucomannan and fish gelatins and encapsulated with the matrine, as a Chinese herbal medicine (Zhou *et al.*, 2020). It was found that using 40 mg/mL of matrine afforded bactericidal inhibition zones 11.5 and 12 mm for the *S. aureus* CMCC(B) 26003 and *E. coli* ATCC25922 bacteria, respectively. Antibacterial and natural wound dressing materials were fabricated using composite sponges of GEL and bacterial cellulose which exhibited exceptional antimicrobial activities against *S. aureus*, *C. albicans* and *E. coli* microorganisms (Ye *et al.*, 2019). To enhance the viability of cryopreserved SaOS-2 cells, porous biocompatible hydrogel composites were developed using blended GEL, sericin and carrageenan loaded by several growth factors and drugs which were utilized in bone regeneration treatments and exhibited enhanced cell attachment and cryopreservation (Ashe *et al.*, 2020). Alendronate, insulin like growth factor, IGF-1, and Ag nanoparticles were separately introduced in the hydrogels and it was shown that the IGF-1 containing composite hydrogel had superior osteogenic cell revival, proliferation and attachment during the cryopreservation along with 55% clonogenic capacity for the seeded SaOS-2 cells and 80% population of live cells in 30 days cryopreservation confirming this hydrogel was a promising material for regeneration and repairing of bones. Several three-dimensional bioprinting composite hydrogels by extrusion method using GEL and alginate hydrogels crosslinked by 2 wt% of CaCl_2 and encapsulated with

human amniotic epithelial cells and Wharton's jelly derived mesenchymal stem cells to be used in regenerative medicine and skin tissue engineering (Liu *et al.*, 2019). It was illustrated that the GEL: alginate ratio of 15:2 wt%: wt% for bioprinting the constructs such as ear and nose afforded high bioprinting resolution of $151 \pm 13.04 \mu\text{m}$ at low temperature of 4°C . Also, high cellular viability of $>95\%$ was measured in 6 days post bioprinting. Some gene delivery systems were fabricated using bioactive electrospun GEL scaffolds loaded with plasmid DNA, pDNA, polyplexes capable of gene expression (Pankongadisak *et al.*, 2020). To prepare the pDNA, polyplexes, the pDNA was mixed with lipid conjugated polyethylenimine to attain polyplexes (size = 82 nm) containing poly(aspartic acid), pAsp, as an additive. The pDNA polyplexes displayed considerably greater transfection capacities within solution as well as when they were entrapped into the electrospun scaffolds according to the GFP expression in the MC3T3-E1 mouse osteoblast and C2C12 human myoblast cells. The gene triggered activities of mats were validated using a pDNA encoded BMP-2 that showed strong induction of alkaline phosphatase within the MC3T3-E1 and C2C12 cells approving their osteogenic

differentiation. Thus, the GEL fibrous mats composed of bioactive pDNA polyplexes were appropriate materials for regenerative repairing numerous tissues. Actuation hydraulic device were fabricated using GEL phantoms which caused 1 Hz motions to investigate the image reconstruction by the intrinsic actuation-magnetic resonance elastography (Gordon-Wylie *et al.*, 2018).

Medical Applications of Gellan Gum, Acacia Gum, Guar Gum, Tamarind Gum and Xanthan Gum Composites

There are numerous gums that are broadly employed in biomedical applications including gellan gum (GG), acacia gum (AG), guar gum (GUG), tamarind gum (TG) and xanthan gum (XG). These materials are natural polysaccharides which can be fabricated as composites in order to improve their physicochemical and structural properties to be satisfactory for the clinical and medical applications. In the following, several biomedical applications of such composite gums are presented.

Fig. 14 Hemostasis in rat liver injury (A1) time for clotting; (A2) blood Loss. ****indicates $p \leq 0.0001$. Nano-biocomposites of GG and TiO_2 nanotubes, NTs, were prepared as wound dressing materials which were satisfactorily biocompatible towards the 3T3 mouse fibroblast cells and exhibited favorable wound healing activities to the open excision wounds created on Sprague Dawley rats (Fig. 16; Razali *et al.*, 2020). Also, the nanocomposite containing 20 w/w% of TiO_2 nanotubes displayed the utmost antibacterial capacity against *Pseudomonas aeruginosa*, *Escherichia coli*, *Streptococcus* and *Staphylococcus aureus* bacteria with inhibition zones were 12 ± 0.25 , 14 ± 0.06 , 16 ± 0.06 and 16 ± 0.06 mm, respectively. Composites of GG and Manuka honey were achieved indicating inherent antibacterial characteristics against *S. epidermidis* and *S. aureus* clinical microorganisms, and greater mechanical properties compared to those of the natural hydrogels such as CS, alginate and HA (Bonifacio *et al.*, 2018). Additionally, they did not reveal cytotoxicity to the human mesenchymal stem cells and displayed constant collagen II expression and large synthesis of proteoglycans and glycosaminoglycans according to the chondrogenesis tests approving the cartilage matrix formation. Hence, such smart biocomposites were considered as promising biomaterials for the cartilage tissue engineering. Some composite were developed based on GG, guar gum and hydroxyapatite through the freeze

drying technique that were applied in bone tissue engineering (Anandan *et al.*, 2019). The optimized scaffold displayed a minimum swelling and only 13.7% degradation in the phosphate buffered saline medium during 21 days. Furthermore, it did not show any cytotoxicity to the MG63 osteosarcoma and L929 murine fibroblast cells because the cells were well proliferated on the scaffold as established using the MTT assay for 1, 4 and 7 days. Nanocomposite films of GG and TiO₂ nanoparticles were achieved

Fig. 16 Macroscopic photographs of the wounds treated using (a) Control, (b) GG, (c) GG + TiO₂ NTs (1 w/w%), (d) GG + TiO₂ NTs (5 w/w%), (e) GG + TiO₂ NTs (10 w/w%), and (f) GG + TiO₂ NTs (20 w/w%) films. Reprinted with permission from Razali, M.H., Ismail, N.A., Mat Amin, K.A., 2020. Titanium dioxide nanotubes incorporated gellan gum bio-nanocomposite film for wound healing: effect of TiO₂ nanotubes concentration. *International Journal of Biological Macromolecules* 153, 1117–1135.

as effective wound dressings which illustrated suitable antibacterial activities with 11 ± 0.06 and 9 ± 0.25 mm growth inhibition zones against *E. coli* and *S. aureus* bacteria, respectively (Bonifacio *et al.*, 2020). Moreover, the GG/TiO₂ nano-biofilm was not cytotoxic to mouse fibroblast cells as it revealed superior migration and proliferation of the cells and accelerated healing of open excision wounds created on Sprague Dawley rats in 14 days but the GG-treated wounds did not completely healed. Biocomposites of GG and high-methoxyl pectin modified with diethanolamine encapsulated the olive oil and used in intra-gastric controlled delivery of metformin HCl so that different drug encapsulation efficiency of 50%–85% and prolonged drug release activities of 69%–94% were measured in acetate buffer with pH = 4.5 (Bera *et al.*, 2018). Three-dimensionally bioprinted high fidelity human scale nose and ear tissues were constructed using GG (with greater shear thinning and recovery) and poly(ethylene glycol)

Fig. 17 Printability of GG/PEGDA hydrogels. (a, c, e) Optical images of printed 3D structures. (b, d, f) The printing fidelity for the bioink candidates. using 100 µg/mL of the composite (Duran *et al.*, 2019). GA was attached to the alginate through covalent bonds and the prepared hydrogen was incorporated with ZnO nanoparticles (Manuja *et al.*, 2020). The nanocomposite was topically used on full-thickness excision wounds in rabbits that revealed wound healing accelerated.

Nanocomposite hydrogels were obtained as wound dressings based on GUG conjugated polyacrylamidoglycolic acid, AgNO₃ and NaBH₄ which were injectable, self-healing and antibacterial materials (Palem *et al.*, 2019). An antibacterial nanocomposite was fabricated using poly(methyl methacrylate) grafted GUG and Zn, Ce substituted hydroxyapatite for application in orthopedics (Priya *et al.*, 2018). It was illustrated that the nanocomposite led to integration/adhesion of human osteoblast cells, augmented development/proliferation of fresh bone and declined the possibility of cartilage structure collapse.

Chronotherapeutic carriers were prepared and loaded by the propranolol HCl drug using several biopolymers like TG, CS and Okra gum for targeted colon drug delivery and treatment of blood pressure at early morning (Newton *et al.*, 2015). The *in vitro* drug release tests were done within 0.1 N HCl for 1.5 h, then in phosphate buffer (pH 6.8) for 2 h and finally in phosphate buffer (pH 7.4) to measure the highest drug release amount. It was found that the formulation fabricated by the TG could prolong the drug release for longer times among other formulations. Several muco-adhesive tea tablets that were orally disintegrated and used in oral care purposes were developed through microwave radiation containing 1 w/w% of TG, GA, GUG, carrageenan or PEC or polysaccharides which exhibited antibacterial activities against *Streptococcus mutans* bacterium (Kiniwa *et al.*, 2019).

Antimicrobial and magnetic patches were achieved using XG, bovine serum albumin, Fe₃O₄ nanoparticles and amoxicillin drug to release the drug through magnetic stimulation (Bueno *et al.*, 2018). The patch contained 0.2 wt% of Fe₃O₄ released *in vitro* the drug at pH 5.5 and 0.02 mol/L of NaCl solution when exposed to the electromagnetic field followed by quasi-Fickian diffusion. The diffusion of drug molecules from patches into the agar including *E. coli* and *S. aureus* bacteria inhibited the bacterial growth. Also, the *E. coli* growth inhibition was especially effective when electromagnetic field was applied. Composite microspheres of XG

and CaCO_3 were fabricated by a mineralization biomimetic technique and used in adsorption of the lysozyme protein (Xu *et al.*, 2018). The microspheres efficiently immobilized the lysozyme through electrostatic attractions adsorption quantity and rate were $18.7 \pm 1.2 \mu\text{g}/\text{mg}$ and $58.55 \pm 0.56\%$, respectively at pH 7.0 but they were $24.3 \pm 0.1 \mu\text{g}/\text{mg}$ and $80.97 \pm 0.15\%$ at pH 9.0.

Medical Applications of Pectin, Collagen and Polyhydroxy Butyrate Composites

The pectin (PEC), collagen (COL) and polyhydroxy butyrate (PHB) composites are valuable biomaterials which are frequently employed in various medical purposes. Herein, several instances are presented to show the importance of such substances.

A porous composite was developed based on PEC, GEL and biphasic calcium phosphate loaded with vascular endothelial growth factor and bone morphogenetic protein-2 (VEGF and BMP-2) to transport growth factors to bones for bone formation/regeneration/healing (Amirian *et al.*, 2015). The scaffolds incorporated with the VEGF and BMP-2 increased the spreading, proliferation and viability of MC3T3-E1 preosteoblasts were investigated relative to the scaffolds prepared without these growth factors. Also, bone formation *in vivo* in rats was happened using the composites containing VEGF and BMP-2 in four weeks which was greater in the BMP-2 loaded scaffold. Magnetic thermo- and pH- dual responsive microgels were prepared using PEC maleate, Fe_3O_4 nanoparticles and N-isopropyl acrylamide that were encapsulated with curcumin drug and used as drug vehicles (Almeida *et al.*, 2017). The curcumin release was sustainable and slow by applying an external magnetic field. Composite films of quaternized PEC and montmorillonite mineral were obtained and loaded with 5-fluorouracil anticancer drug as drug delivery formulations (Meng *et al.*, 2020).

A composite of COL and octacalcium phosphate was fabricated as an implant to induce the bone regeneration in bone defects of rodent, canine and human (Kanda *et al.*, 2016). It was found that the implantation inside the alveolar area including the unerupted permanent successor teeth was disturbed the permanent tooth eruption but preserved the alveolar ridge (Figs. 19 and 20). Magnetic COL nano-biocomposite was developed as the MRI contrast agent and as a targeted carrier for application in cancer treatment (Mandal *et al.*, 2013). The COL nanofibers were fabricated using Fe_3O_4 nanoparticles, fluorescein isothiocyanate labeled antibody and gemcitabine anticancer drug. This NBC was characterized by conventional methods and evaluated for its biological activities. The MRI scan indicated a superparamagnetic property for the COL nanocomposite confirming it was a good MRI contrast agent. The MTT test approved that the COL nanobiocomposite was biocompatible towards the Hep2 Human epithelial type 2 cells but it exhibited an apoptotic influence by the receptor assisted endocytosis and cellular uptake.

Fig. 19 (a) Implantation processes, (b) before tooth extraction, (c) preparation of implant beds after removing the alveolar septum of the Dp2 and Dp3 (untreated group), (d) implantation of OCP/Col (OCP/Col group), (e) implantation of β -TCP (β -TCP group); Dp2: second deciduous premolar, Dp3: third deciduous premolar, P3: third premolar, P4: fourth premolar, M1: first molar. Reprinted with permission from Kanda, N., Matsui, K., Kawai, T., *et al.*, 2016. Implantation of octacalcium phosphate collagen composites (OCP/Col) after extraction of canine deciduous teeth achieved undisturbed permanent tooth eruption. Archives of Oral Biology 72, 179–186.

Fig. 20 Radiographic images indicating the OCP/Col tends to have eruptive positions of the third and fourth premolars (P3 and P4) and alveolar heights which are comparable to those of Physiol. The β -TCP and untreated groups tend to have lower eruptive positions of the third and fourth premolars and alveolar heights. Bars: 20 mm. Reprinted with permission from Kanda, N., Matsui, K., Kawai, T., *et al.*, 2016. Implantation of octacalcium phosphate collagen composites (OCP/Col) after extraction of canine deciduous teeth achieved undisturbed permanent tooth eruption. *Archives of Oral Biology* 72, 179–186.

Composite scaffolds of PHB-co-hydroxyvalerate copolymer conjugated graphite oxide and Fe_3O_4 nanoparticles were synthesized that were thermally and mechanically stable and employed in tissue engineering and bio-imaging by acquisition of phantom agar MRI images due to the existence of the Fe_3O_4 nanoparticles used as a negative T2 contrast material with greater relaxivity (Pramanik *et al.*, 2019). The Composite scaffolds exhibited higher antibacterial properties against Gram-negative strains (*E. coli* and *P. aeruginosa*) than Gram-positive bacteria (*B. subtilis* and *S. aureus*). Noteworthy adhesion as well as 85% proliferation of NIH 3T3 fibroblast cells were observed onto the nanocomposite surface indicating its biocompatibility and physiological stability. Bionanocomposites of PHB and Co_3O_4 were fabricated which illustrated the highest bactericidal activities against *S. aureus* and *E. coli* as multidrug resistant microbes (Safaei *et al.*, 2020). Porous composites of PHB and hydroxyapatite (HAP) were fabricated containing various amounts of HAP including 10, 20, 30, 40, 50 wt% (Senatov *et al.*, 2017). The PHB-20%HAP and PHB composites were *in vitro* adhered onto the mouse multipotent mesenchymal stromal cells so that the PHB-20% HAP more effectively induced proliferation of cells ($31 \pm 6.1\%$) than PHB ($20 \pm 5.7\%$). The PHB-20%HAP composite was resorbed (indicating 49% decrease in the implant surface area) and integrated to the neighboring tissues 30 days post implantation. Also, accumulation of osteoclasts, angiogenesis and formation of fresh bone proved that the PHB-20%HAP was a favorable material in bone tissue engineering. The PHB polymer was isolated from *Bacillus cereus* strain VIT-SSR1 using a contaminated industrial waste and the PHB/CS blended films encapsulated with the curcumin drug were fabricated which indicated a sustained drug release and their biocompatibility were examined by the MTT test using L929 mouse fibroblast cells (Evangeline and Sridharan, 2019).

Conclusion

Natural biopolymers and their composites can replace the synthetic polymers as the fossil fuel based polymers reveal numerous side effects. It has been recognized that the synthetic petroleum derived polymers have many unfavorable environmental issues. Also, they are usually left at landfills, soils and oceans without degradation leading to the environmental pollution. Therefore, biodegradable polymers can be used to solve these contaminations. Moreover, biopolymers and their composites are increasingly employed in therapeutic and surgical applications, tissue regeneration, biomedicine, drug carriers, radiotherapy, imaging and diagnosis, temporary prostheses, adhesion/fixation/suturing biomaterials and implants. The biopolymers marketplace grows quickly by enhancement in the social attention to the sustainable environment. Although utilization of synthetic polymers (and plastics) instead of the biopolymers is an important subject, the production of biopolymers in large scales still is not cost effective. Thus, it is necessary to perform more extensive investigations to find economical methods for the synthesis or fabrication of biopolymers and their composites from biomasses.

Biological polymers and their composites exhibit several benefits compared to the extensively utilized synthetic polymers because they are biocompatible, bioactive, biodegradable, renewable, environmentally benign and may reveal antibacterial/anti-inflammation capacities. For instance, biopolymer composite scaffolds have been used in clinical trials to repair the bone, skin, cartilage, human organs and vascular grafts, completely bio-barrier membranes and absorbable stents without needing subsequent surgery. Moreover, biopolymer composites are developed as systems releasing bioactive agents and drugs as multifunctional formulations preserving the properties of all encapsulated biomolecules.

Most biopolymers illustrate poor mechanical features relative to those of the synthetic polymers. Thus, different procedures are adopted to improve their mechanical properties including adding nano/micro-particles as fillers, plasticizers, and conjugating biopolymers and/or biopolymer blends. Natural biopolymers are mostly incorporated with bioactive substances, nano/micro-materials and/or other polymers

in order to achieve matrixes well mimicking the ECM. Numerous biopolymers are commonly commercially employed by researchers and industries such as chitosan, carboxymethyl chitosan, alginate, hyaluronic acid, cellulose, carboxymethyl cellulose, starch, carboxymethyl starch, gellan gum, gum acacia/gum arabic, guar gum, tamarind gum, xanthan gum, gelatin, zein, chondroitin sulfate, polyhydroxy butyrate, pectin and collagen. It has been frequently shown that incorporation of inorganic nano-/micro-materials as fillers improves the physical and structural characteristics of biopolymers such as their moisture sensitivity, gas permeability, mechanical strength, shelf life, antifungal and antibacterial activities. The biopolymer composites are extensively utilized in different biomedical applications such as surgical implants, drug delivery formulations, vaccines, tissue engineering, imaging and diagnosis though they have found numerous other applications including smart materials, packaging, electronics, food products, construction, biosensors, conductive and antibacterial papers and textiles.

Introduction

Acrylic acid was first discovered in 1843 and then led to the formulation of methacrylic acid (MA) in 1865 (Hendriks *et al.*, 2004). The chemical reaction of MA with methanol leads to the formation of methyl methacrylate (MMA), which is the constitutional monomer of poly(methyl methacrylate) (PMMA) (Markatos *et al.*, 2010; Breusch and Malchau, 2005). PMMA was first utilized in arthroplasty by the Judet brothers in the 1950s when they fabricated femoral heads from PMMA (Judet and Judet, 1950), even though it was failed biologically and mechanically (Breusch and Malchau, 2005; Ayre, 2013). In 1953, utilizing PMMA as a grout for enhancing the implant fixation in bone (Haboush, 1953) was followed by Sir John Charnley in 1958, who succeeded to anchor a femoral head prosthesis in a femur through auto-polymerization of PMMA (Charnley, 1960). This eventuated in an entirely novel surgical technique whereby acetabular and femoral implants could be fixed to the bone by PMMA during hip replacements (Charnley, 1970). Today, loading antibiotics such as gentamicin, penicillin, and erythromycin in cement is still followed with gentamicin in bone cements (BCs) (Ayre, 2013; Buchholz, 1970; Soleymani Eil Bakhtiari *et al.*, 2020b). Commercial PMMA-based BCs consist of two phases, including a liquid monomer and a solid powder, in which their combination leads to form polymer chains through a free-radical polymerization process. In commercially available PMMA-based BCs, the liquid phase contains MMA, N,N-Dimethyl-p-Toluidine (DMPT) as an activator, and a small amount of hydroquinone as a polymerization inhibitor for the monomers during storage. The powder component consists of PMMA polymer particle, barium sulphate (BaSO_4), or zirconium dioxide (ZrO_2) as a radiopaque factor for visibility under X-ray imaging and benzoyl peroxide (BPO) as an initiator for the polymerization reaction (Kuehn *et al.*, 2005). This kind of BCs is a polymeric material that presents great cytocompatibility and offers outstanding preliminary fixation among bone and implant. Nevertheless, it has certain drawbacks such as escalating in temperature throughout the polymerization, which might result in bone cell necrosis as well as implant loosening and inadequate mechanical characteristics, lack of bone formation, and bioactivity, which often may lead to failure of the bone cement (BC). As a consequence of the high utilization of BCs, numerous researchers have made attempts to remove the issues of BCs. To be able to enhance and restore the PMMA-based BCs, several ceramic, polymer, and composite reinforcement agents have been employed. Despite the fact that numerous articles are previously published concerning PMMA-based BC (Dunne and Ormsby, 2011; Ormsby *et al.*, 2010; Huang *et al.*, 2005) a few articles are observed, which specifically examined PMMA-based composite BCs with various kinds of additive agents for orthopedic applications. This study describes PMMA-based BC development in the previous years concerning filler for skull bone and bone cavity. On top of that, we will review the latest advancements based on the kind of additive agent employed for preparing PMMA-based composite BCs. In addition the effect of carbon based materials incorporation on the mechanical and cellular response of BCs, comparing their effectiveness was reviewed in this study, which is barely studied before. The purpose is to depict the demands of the right choice of additives agents for PMMA-based BCs, so we will realize the current status and understand the forthcoming requirements of this field. Fig. 1 shows the chemical structure of MMA liquid and PMMA powder in the PMMA-based BCs (Dunne *et al.*, 2014).

Properties of the PMMA-Based BCs

Handling Properties

Four different phases can describe the curing process of the PMMA-based BCs with their related viscosities, including mixing, waiting, working or application, and hardening or setting (Dunne and Orr, 2002; Lewis, 2003). The *mixing phase*, which takes up to 1 min, is the time for the entire homogenization of the polymer powder with the liquid components. The *waiting phase* lasts up to

Fig. 1 Chemical structures of MMA liquid and PMMA powder in the PMMA-based BCs. Adapted from Dunne, N., Clements, J., Wang, J.S., 2014. Acrylic cements for bone fixation in joint replacement. In: Joint Replacement Technology. Woodhead Publishing, pp. 212–256.

several minutes. The cement turns into a non-sticky state at this stage, thus, ready to use. In the *working or application phase*, which lasts 2–4 min depending on the type of BC and curing temperature, the cement is injected into the bone prior to implantation of the prosthesis. The *hardening or setting phase*, which lasts 1–2 min, is the last stage leading to an exothermic polymerization interaction producing heat. At the end of the setting phase, the heat produced through polymerization will drop back to ambient temperature (Dunne *et al.*, 2014; Soleymani Eil Bakhtiari *et al.*, 2020a).

Thermal Properties

Once the liquid and powder components are mixed, BPO reacts with *N,N*-DMPT to create free radicals, called the “initiation reaction”, leading to polymerizing MMA into PMMA through incorporating the polymerizable double-bond of the monomer molecule (Dunne and Ormsby, 2011; Huang *et al.*, 2005; Soleymani Eil Bakhtiari *et al.*, 2020b). Exothermicity is significantly critical for the process of polymerization. The point that the heat rises connected to the cement mantle thickness, the room temperature, and the weight percentage of polymer to monomer has been shown *in vitro*. The calculated value range between 70 and 120°C; but then again, the *in vivo* examination exhibited are luckily the minimum value between 40 and 56°C, reflecting the threshold values beyond which may induce protein coagulation with associated biological destruction (osteonecrosis) (Magnan *et al.*, 2013; Webb and Spencer, 2007). The *in vivo* thermogenesis of BCs may lead to thermal necrosis of the bone cells and cell damage in the binding sites, which may cause a premature failure through the aseptic loosening of the implant (Dunne and Ormsby, 2011; Huang *et al.*, 2005). Setting properties of BCs are carried out according to the ISO5833:2002 and ASTM F451–99a standards (Standard, 2002, 2006).

Mechanical Properties

PMMA-based BCs mainly present an anisotropic mechanical function through evenly distributing and transferring the mechanical stresses from the implant to the bone (Charnley, 1970; Dunne *et al.*, 2014). Clinical cement from PMMA is brittle in nature. It is fragile in stress, like other brittle components, but very strong under compression. Typically, compressive strength ranges from 44 to 103 MN/m². This really is about 50%–70% of the cortical bone’s mechanical property. The elasticity modulus is stated to have ranged from 2140–3100 MN/m². The intensity of this module was almost one order lower than the average cortical bone. The amounts’ differences are primarily attributed to the variations in the loading rate or strain during testing and the elements connected with the sample preparation process. PMMA-based BC is employed to restore pathological bone injuries and bony disorders when subjected to bending impact. Hence it is beneficial to find out its bending or flexural strength for the development of such clinical use (Saha and Pal, 1984). Determining the compressive, bending and fracture toughness properties of PMMA-based BCs are performed according to ISO5833:2002, ASTM F451–99a and ASTM E399 standards (Standard, 2002, 2006, 1989).

Fig. 2 Chemical structure of HA. Adapted from Mostafa, N.Y., Brown, P.W., 2007. Computer simulation of stoichiometric hydroxyapatite: Structure and substitutions. *Journal of Physics and Chemistry of Solids* 68 (3), 431–437.

Biological Properties

Since PMMA-based BCs are biologically inert, they do not contribute to the surrounding bone's growth and regeneration. Thus cement-bone interface connection is weak. Several studies attempted to enhance the biocompatibility of BC. To enhance cytocompatibility and apatite formation ability of PMMA surface when it is exposed to the bone environment, the bioactive phases such as hydroxyapatite (HA) (Kim *et al.*, 2004; Wolf-Brandstetter *et al.*, 2013) or bioglass (Heikkilä *et al.*, 1996; Rhee *et al.*, 2003; Shinzato *et al.*, 2004; Wolf-Brandstetter *et al.*, 2013) encapsulated into the PMMA-based BC. The purpose was to have the bone nearer to the cemented implant and thereby to minimize micromotions that are considered necessary for recovery and stabilization (Sundfeldt *et al.*, 2006). For clinical success, the contact between the metal implant surface and the BC also plays a crucial role (Jasty *et al.*, 1991; Wolf-Brandstetter *et al.*, 2013). Incorporating bioactive agents in formulation leading to an enhancement in the biocompatibility of BCs, thus reducing the formation of fibrous tissue at the bone-cement interface (Dunne and Ormsby, 2011; Jimenez, 2017).

Current Problems Related to the PMMA-Based BCs

Although PMMA-based BCs have desirable properties such as appropriate biocompatibility and excellent initial fixation between bone and implant, they have some drawbacks such as lack of bone formation, lack of bioactivity, and poor mechanical properties leading to failure the BCs. In order to enhance the mechanical, biological, and bioactivity properties of PMMA-based BCs, many researchers have made efforts to resolve their weakness through adding different kinds of ceramic, polymer, or a composite of them as reinforcements. The most common reinforcements used to improve PMMA-based BCs are discussed below.

Different Types of Reinforcements in the PMMA-Based Composite BCs

Hydroxyapatite (HA)

In human bone tissue, HA possesses a comparable chemical property to apatite and can join the host bone tissue (Harakas, 1984; Quan *et al.*, 2016). The additive phase incorporated into PMMA-based BC broadly to escalate cell viability and bioactivity (Kalita *et al.*, 2007; Quan *et al.*, 2016). The chemical structure of HA is shown in Fig. 2 (Mostafa and Brown, 2007). HA powder is an appropriate reinforcement for organic polymers, mechanically, and biologically. HA is a biocompatible, osteoconductive, and osteophilic biomaterial (Ogiso, 1992). It is reported that HA particles can present a bone formation due to an ingrowth in bone-forming cells when they were placed next to a viable bone. Various authors have reported encouraging results about adding particulate HA to commercial BCs (Lee *et al.*, 1997; Liebendörfer *et al.*, 1995; Perek and Pilliar, 1992; Harper *et al.*, 1995; Soleymani Eil Bakhtiari *et al.*, 2020b).

Carbon-Based Nanomaterials (CBNs)

Carbon nanotubes (CNTs) and graphene oxide (GO) are the most popular CBNs (Rajakumar *et al.*, 2020; Cha *et al.*, 2013). CNTs, discovered by the Japanese scientist Iijima in 1991 (Iijima, 1991), are now turned to a top-class subject either in academic researches and other industrial areas. This kind of carbon allotropy, composed of graphite, has been produced in cylindrical tubes with a diameter in a nanometer scale and a length in several micrometers (Hirlekar *et al.*, 2009; Singh *et al.*, 2012). CNTs structures are classified into two types depending on the number of layers, including single-walled carbon nanotubes (SWCNTs) and multi-walled carbon nanotubes (MWCNTs). Their desirable and specific structural, mechanical, and electronic properties are related to their tiny size, light mass, high mechanical strength, electrical and thermal conductivity (Usui *et al.*, 2012; Zhang *et al.*, 2010; Soleymani Eil Bakhtiari *et al.*, 2019). Another important CBNs is GO. In specific, due to its favorable aqueous durability,

Fig. 3 Structure of (a) SWCNTs (b) MWCNTs (c) GO (d) Graphene sheet. Adapted from Ahmed, N., Khan, U., Mohyud-Din, S.T., 2020. Modified heat transfer flow model for SWCNTs-H₂O and MWCNTs-H₂O over a curved stretchable semi infinite region with thermal jump and velocity slip: A numerical simulation Physica A: Statistical Mechanics and its Applications 545, 123431. Doi, Y., Nakatani, A., 2011. Structure and stability of nonlinear vibration mode in graphene sheet. Procedia Engineering 10, 3393–3398.

amphiphilicity, surface functionality and property, and fluorescence quenching capacity, GO chemically exfoliated from oxidized graphite is regarded as a viable component for biological purposes (Chung *et al.*, 2013). GO can have appropriate physical and chemical interactions with biopolymers. Moreover, it has appropriate biocompatibility to consume in medicine due to its carbonyl, carboxyl, and hydroxyl groups (Tavakoli and Karbasi, 2020b; Depan *et al.*, 2014; Soleymani Eil Bakhtiari *et al.*, 2020a). It is reported that the three carbon nanostructures, including CNTs, graphene (G), and GO play an important role in cell behavior and mechanical properties (Soleymani Eil Bakhtiari *et al.*, 2019; Liu-Snyder and Webster, 2008; Novoselov *et al.*, 2004; Compton and Nguyen, 2010; Lam *et al.*, 2004; Pahlevanzadeh *et al.*, 2019a; Soleymani Eil Bakhtiari *et al.*, 2020a). The structures of CNTs, GO, and G sheet are shown in Fig. 3 (Ahmed *et al.*, 2020; Doi and Nakatani, 2011).

Chitosan

Chitosan (CS) is another reinforcement used in the PMMA-based BCs. CS, as one of the most functional polymers, is a natural linear polysaccharide derived from chitin. It can be extracted from the exoskeletons of shrimp, crab, and the cell wall of fungi (Soleymani Eil Bakhtiari *et al.*, 2019; Jaafari *et al.*, 2004). The chemical structure of chitin and CS are shown in Fig. 4 (Kumar, 2000). CS is a biodegradable copolymer composed of N-acetyl glucosamine and D-glucosamine (Yuan *et al.*, 2010). It is a biomaterial used in medical applications due to its desirable properties such as low toxicity, excellent biocompatibility, biodegradability, anticoagulation, wound healing, and antibacterial properties (Jayakumar *et al.*, 2011; Venkatesan and Kim, 2010; Parvizifard *et al.*, 2020). The effects of CS on the PMMA-based BCs are reported in many studies. Intramolecular hydrogen bonds existed in CS provide a series of reactive heat resistance macromolecules (Endogan *et al.*, 2014).

Effect of Different Reinforcements on Setting Properties

The effect of different reinforcements on the setting process of the PMMA-based composite BCs are tabulated in Table 1. According to the table, the setting properties of PMMA-based composite BCs including HA, glass ceramic (GC), HA/CS, MWCNTs, functionalized MWCNTs (f-MWCNTs), CS, quaternized CS, GO, CS/MWCNTs, CS/GO, CS/ β -tricalcium phosphate (β -TCP), SiO₂, SiO₂/Tri-calcium phosphate (TCP), SiO₂/hydroxyethyl methacrylate (HEMA), ethylene glycol dimethacrylate (EGDMA), TCP/CS, polycaprolactone (PCL), PCL/baghdadite (BAGH), MgO, calcium silicate, cellulose, Mg, polydioxanone (PDO) and sodium polyacrylate short fibers (PAAS_f) were evaluated.

In a study by Samad *et al.* (2011) application of new bioactive GC in PMMA-based BCs was evaluated. The obtained results showed as the concentration of the reinforcement phase (HA and GC) amplified, the peak temperature throughout the setting response diminished and all filled BCs presented a lower peak temperature compared with the reference specimen, but overall PMMA-based BCs containing 4 and 8 wt% GC filler loading exhibited optimum setting and handling properties (Samad *et al.*, 2011). In another study Ferreira *et al.* (2014) evaluated the properties of novel PMMA-based BCs filled with HA. According to the results obtained from adding 25 wt% HA to the PMMA-based BC, it can be concluded that the partial substitution of commercial PMMA beads by commercial HA decreases the values of peak temperature while increases the setting time (Ferreira *et al.*, 2014). In other study by Kim *et al.* (2004), the characteristics of PMMA-HA/CS-based BCs were investigated. It was reported that a decreased thermogenesis and an increased setting time can be achieved in the PMMA-HA/CS-based BCs in comparison with a pure PMMA-based BC (Kim *et al.*, 2004). In a study by Ormsby *et al.* (2010), the effects of MWCNTs on mechanical and thermal properties of

Fig. 4 Chemical structures of Chitin and Chitosan. Adapted from Kumar, M.N., 2000. A review of chitin and chitosan applications. *Reactive and Functional Polymers* 46 (1), 1–27.

PMMA-based BCs were evaluated. Obtained results showed that adding the thermally conductive *f*-MWCNTs to the PMMA-based BCs significantly reduced the heat produced in the exothermic polymerization reaction of the BCs and they also significantly increased the setting time of BCs (Ormsby *et al.*, 2010; Soleymani Eil Bakhtiari *et al.*, 2020a). In another study, Endogan *et al.* (2014) evaluated the effects of the PMMA powder size and CS addition on the properties of PMMA-based BCs. Obtained results showed that adding CS to the PMMA-based BCs containing PMMA powder with particle size in the range of 50–150 μm , leads to a decrease in polymerization temperature (Endogan *et al.*, 2014). In other study by Tan *et al.* (2012), novel PMMA/quaternized CS-based BC was fabricated and its setting properties were evaluated. The results of PMMA/quaternized CS-based BC presented modified properties such as a lower curing temperature and more prolonged setting time in comparison with other PMMA-based BCs (Tan *et al.*, 2012). Valencia Zapata *et al.* (2020) and Zapata *et al.* (2020) fabricated cement containing CS for biomedical fields. Their result exhibited the alteration of setting characteristics, such as reduced maximum temperature and escalation in setting time (Valencia Zapata *et al.*, 2020; Zapata *et al.*, 2020). In this regard, throughout the MMA polymerization reaction, the maximum temperature attained showed a diminishing of 13°C with a 20% CS loading, and the increase in setting time was significant for formulations with CS loading ≥ 15 wt% (Valencia Zapata *et al.*, 2020). The incorporation of CS and GO individually or jointly in BC composition, likewise elevated setting characteristics (Zapata *et al.*, 2020). The reduction in the maximum temperature with an enhancement in CS encapsulation results from the heat sink serving as intramolecular hydrogen bonds in CS (Endogan *et al.*, 2014). In another studies by Soleymani Eil Bakhtiari *et al.* (2020c) and Tavakoli *et al.* (2020a) the effects of CS powder, CS/MWCNTs and CS/GO composite powder on physical, mechanical and biological properties of PMMA-based BCs were investigated. Obtained results showed that adding CS powder, CS/MWCNTs and CS/GO composite powder to the PMMA-based BCs increased setting time and decreased maximum temperature, significantly (Soleymani Eil Bakhtiari *et al.*, 2020a,c; Tavakoli *et al.*, 2020a). In other study by Lin *et al.* (2005), the effects of CS/ β -TCP microspheres on setting and mechanical properties of PMMA-based BCs were evaluated. Obtained results of the PMMA/CS- β -TCP-based BCs showed that adding CS/ β -TCP in the form of microspheres significantly decreased the maximum curing temperature and delayed the final cure, thus more manipulating time for the operation (Lin *et al.*, 2005). In other study by Yang *et al.* (1997), PMMA/SiO₂-based BCs containing different reinforcements were fabricated. Obtained results showed that in PMMA/SiO₂-based composite BCs, adding TCP to the BCs led to an increase in setting time and decrease in maximum curing temperature, while adding HEMA and EGDMA to the PMMA/SiO₂-based BCs reversely affected the BCs (Yang *et al.*, 1997). In another study (Tsukeoka *et al.*, 2006), modifying PMMA-based BCs by γ -methacryloxypropyltrimethoxysilane (MPS) and calcium acetate presented an increased setting time, while a lower curing temperature (Tsukeoka *et al.*, 2006). In another study by Fang *et al.* (2019), PMMA-based composite BCs containing TCP/CS were prepared. Obtained results indicated that by adding TCP/CS to the PMMA-based BCs, the curing temperature of BCs was

Table 1 Setting properties of PMMA-based composite BCs containing different types of reinforcements

Sample of BCs	Maximum temperature (°C)	Setting time (sec)	Reference
PMMA	52.90	740.40	(Samad <i>et al.</i> , 2011)
PMMA/4 wt% HA	47.60	780.00	(Samad <i>et al.</i> , 2011)

decreased, and longer setting time was achieved (Fang *et al.*, 2019). In another study by Pahlevanzadeh *et al.* (2019b) adding BAGH to the PMMA/PCL-based BCs led to an increase in setting time and decreased temperature (Pahlevanzadeh *et al.*, 2019b). In a study by Khandaker and Meng (2015) the PMMA-based BC containing 2 wt% MgO indicated a significantly lower curing temperature than other samples having MMA monomer only (Khandaker and Meng, 2015). The results obtained from the constructed PMMA/calcium silicate hybrid-based BCs showed that the curing temperature was substantially lower than the pure PMMA-based BC (Sun *et al.*, 2019). In another research carried out by Wekwejt *et al.* (2020), several modifier phases incorporated to neat PMMA-based BC, composed of cellulose, CS, Mg, PDO, and TCP. The outcomes revealed which the encapsulation of

modifiers did not tremendously impact BC's setting characteristics. All modified BCs had a curing period of 13–17 min and an maximum polymerization temperature in the range of 34–42°C (Wekwejt *et al.*, 2020). In addition, injectable PMMA-based BCs containing short fiber were prepared by Tang *et al.* (2017). The outcomes highlighted that the PMMA-based BC curing time was 12.9 min, and the maximum temperature had been 83.10°C. It is worth noting that, curing times for BCs containing short fiber amplified with the escalating short fiber amount, although the maximum temperature diminished (Tang *et al.*, 2017).

Effect of Different Reinforcements on Mechanical Properties

The mechanical properties of the PMMA-based composite BCs containing different reinforcements including HA, Brushite, HA/CS, MWCNTs, *f*-MWCNTs, CS, gentamicin/CS, CS/GO, CS/MWCNTs, CS/ β -TCP, SiO₂, SiO₂/TCP, SiO₂/HEMA, SiO₂/HEMA/ EGDMA, TCP/CS, PCL, PCL/BAGH, calcium silicate, mineralized collagen (MC), G, GO, PCL/Fluorapatite (FA), PCL/GO, PCL/FA/GO, magnesium phosphate (MgP), TiO₂, mesoporous silica nanoparticles (MSNs), gold nanoparticles (AuNPs) and PAAS_f are tabulated in Table 2.

HA as a reinforcement phase can enhance the mechanical properties of PMMA-based BCs. In the study by (Ferreira *et al.*, 2014) obtained results indicated that bending elastic modulus increased in all samples containing HA particles (Ferreira *et al.*, 2014). In a study by Aghyarian *et al.* (2014), new PMMA-HA/Brushite-based BCs were prepared for spinal augmentation. It was reported that PMMA-HA/Brushite-based BCs presented an average compressive strength of 85 MPa and flexural strength of 65 MPa, which is high mechanical strength even at high contents of calcium phosphate fillers (Aghyarian *et al.*, 2014; Soleymani Eil Bakhtiari *et al.*, 2020b). In another study by Ayatollahi *et al.* (2018), the tension-shear fracture behavior of PMMA/HA-based BCs was evaluated. The fracture behavior of PMMA/HA-based BCs affirmed that adding HA up to 10 wt% to the PMMA-based BCs lead to an increase in the fracture toughness of BCs in all modes. However pure BC showed the greatest fracture resistance among all samples (Ayatollahi *et al.*, 2018; Soleymani Eil Bakhtiari *et al.*, 2020b). In other study by Zebarjad *et al.* (2011), mechanical properties of PMMA/HA-based BCs were investigated. The compression results disclosed that the encapsulation of 2.5 wt% HA to the PMMA-based BC escalated both compressive strength and modulus, and the bending results similarly revealed that the BC containing 2.5 wt% HA presented great bending strength compared to the BC without HA (Zebarjad *et al.*, 2011; Soleymani Eil Bakhtiari *et al.*, 2020b). In another study (Kim *et al.*, 2004) mechanical assessment of PMMA-HA/CS-based BCs before degradation indicated lower ultimate compressive strength (UCS) than pure PMMA-based BC and after degradation showed both the compressive Young's modulus and UCS were significantly decreased (Kim *et al.*, 2004). In general, the enhancement of mechanical characteristics of the PMMA/HA-based composite BCs could be attributed to the uniform distribution of small amounts of the HA particles in the PMMA matrix that act as load carriers. However, the extra content of HA leads to reverse results due to the non-uniform distribution of the HA particles and subsequent agglomeration of them and weak adhesion to the matrix, thus reducing the mechanical properties (Ferreira *et al.*, 2014; Aghyarian *et al.*, 2014; Ayatollahi *et al.*, 2018; Zebarjad *et al.*, 2011; Kim *et al.*, 2004; Soleymani Eil Bakhtiari *et al.*, 2020b). MWCNTs as another reinforcement can improve the mechanical properties of PMMA-based BCs. In the study by (Ormsby *et al.*, 2010) the obtained results from mechanical tests of PMMA/MWCNTs-based BCs showed that improvements in mechanical properties which is attributed to arresting/retarding crack propagation in the BC related to the MWCNTs through bridging the crack wake along with the perpendicular direction of the crack growth. In contrast, lessening in mechanical characteristics were attributed to MWCNTs agglomerations taking place throughout the BC structure. Moreover, these agglomerations' level was relying on the technique employed to encapsulate the MWCNTs into the BC (Ormsby *et al.*, 2010; Soleymani Eil Bakhtiari *et al.*, 2020a). In another studies (Marrs, 2007; Xu *et al.*, 2013), the obtained results from PMMA/MWCNTs-based BCs, also showed that specific MWCNTs loadings could favorably improve the mechanical performance of BCs, which can be attributed to the arresting/retarding crack propagation of MWCNTs through providing a bridging effect and preventing the crack propagation (Marrs, 2007; Xu *et al.*, 2013) and obtained results from the study was done by Xu *et al.* (2013) also showed that the *f*-MWCNTs were a promising additive to improve the compressive and bending strengths of the PMMA-based BC (Xu *et al.*, 2013). CS is another common reinforcement for PMMA-based BCs. According to the obtained results from ref (Endogan *et al.*, 2014), it can be concluded that the utilization of diverse sizes of PMMA particles did not have a significant effect on the mechanical properties of BCs, but adding CS to PMMA-based BCs had a positive effect on the compressive strength (Endogan *et al.*, 2014). In another study, PMMA/CS-based BCs were prepared by Tunney *et al.* (2008) and their mechanical properties were evaluated. Obtained results indicated that after a degradation period of 7 days, a gentamicin-loaded PMMA-based BCs containing CS presented a compressive and bending properties lower than the value required by ISO, which is 70 MPa for compressive strength and 50 MPa for bending strength (Tunney *et al.*, 2008). In other study by Valencia Zapata *et al.* (2019), novel PMMA-CS/GO-based BC was fabricated. Obtained results indicated that some hydrogen-bond interaction between the CS and the GO amplified the mechanical reinforcement in the PMMA-CS/GO-based BC compared to PMMA/CS-based BC and led to a compression resistance in the BC (Valencia Zapata *et al.*, 2019). In another study Valencia Zapata *et al.* (2020) depicted that the minimum bending strength was attained just in the composition without CS. All other compositions provided the minimum bending modulus except for the composite encapsulated with 20 wt% CS and BCs with a composition containing 15 and 20 wt% CS did not experience the minimum compressive strength (Valencia Zapata *et al.*, 2020). In another study by Zapata *et al.* (2020), the addition of 15 wt% CS than that of reference BC, a mechanical characteristic such as compressive, bending strengths and bending modulus were considerably diminished ($p < 0.01$); but when 15 wt% CS was encapsulated along with 0.3 wt% GO, compressive strength lessened substantially, even though it still stayed at greater than 70 MPa, which usually is the minimum value

Table 2 Mechanical properties of PMMA-based composite BCs containing different types of reinforcements

permitted by the standard. However for the BC that contained both CS and GO, bending strength was not significantly different with respect to reference BC. Alternatively, the encapsulation of GO into BCs did not cause any significant enhancement in mechanical performance in comparison with the BCs reference specimen (Zapata *et al.*, 2020). In another study by Soleymani Eil Bakhtiari *et al.* (2020c) adding 25 wt% CS/MWCNTs composite powder to the PMMA-based BCs significantly increased the compressive and bending strength (Soleymani Eil Bakhtiari *et al.*, 2020a,c). Furthermore, in another study by Tavakoli *et al.* (2020a) adding 25 wt% of CS/GO composite powder to the PMMA-based BCs also increased the compressive strength by 16.2%, the compressive modulus by 69.1%, and the bending strength by 24.0% (Tavakoli *et al.*, 2020a; Soleymani Eil Bakhtiari *et al.*, 2020a). In another study (Lin *et al.*, 2005), the UCS and bending strength were decreased due to the presence of CS/ β -TCP microspheres in PMMA-based BCs (Lin *et al.*, 2005). Moreover, in another study by Yang *et al.* (1997) adding TCP to PMMA/SiO₂-based BCs caused to decrease in compressive and bending strengths, but the addition of HEMA and EGDMA in the new BCs had the opposite effect of TCP (Yang *et al.*, 1997). As for modified PMMA-based BCs (Tsukeoka *et al.*, 2006), the modified BCs without soaking in simulated body fluid (SBF) had almost the same compressive strength as the conventional ones, but soaking in SBF decreased the strength unlike the value recommended by ISO5833 (70 MPa). The compressive strength of the Modified BCs is possibly diminished by calcium acetate and section of the hydrolyzed MPS (Tsukeoka *et al.*, 2006). In another study conducted on the PMMA-TCP/CS-based BCs by Fang *et al.* (2019), adding TCP and CS into the pure PMMA-based BC led to decreased compressive Young's modulus and UCS in comparison with the pure PMMA-based BC (Fang *et al.*, 2019). In another study by Pahlevanzadeh *et al.* (2019b) incorporating 20 and 40 wt% BAGH into the PMMA/PCL-based BCs increased the compressive strength and elastic modulus of the BCs (Pahlevanzadeh *et al.*, 2019b). In the study by Sun *et al.* (2019), bioactive injectable PMMA/calcium silicate-based BCs were prepared for percutaneous vertebroplasty and kyphoplasty. Obtained results indicated that PMMA/calcium silicate hybrid BCs sufficiently retained the mechanical strength in comparison with the pure PMMA-based BC, but obtained results from Young's modulus indicated that by adding calcium silicate into the PMMA-based BC, lower Young's modulus achieved (Sun *et al.*, 2019). In another study (Li *et al.*, 2015), the mechanical properties of PMMA/MC-based BCs revealed that the presence of 15 wt% impregnated PMMA-MC significantly decreased compressive modulus, although a little effect on compressive strength and solidification (Li *et al.*, 2015). In other study by Wekwejt *et al.* (2020), the compressive strength evaluation of PMMA-based BCs revealed that the encapsulation of Mg and TCP failed to impact the compressive strength of the BCs; although CS, cellulose, and PDO decreased substantially compressive strength of PMMA-based BCs by 13%, 17% and 24%, respectively (Wekwejt *et al.*, 2020). In another study by (Paz *et al.*, 2017), it was reported that the mechanical behavior of PMMA/G and PMMA/GO-based BCs had been enhanced at low loadings of (≤ 0.25 wt%) due to G and GO-induced deflection in fronts of the crack, which can inhibit the crack from propagation (Paz *et al.*, 2017). Compared to G, the modified GO led to greater improvements considering that it enabled the development of greater interfacial attachment among the GO and PMMA. As a result of the emerging of agglomerates and escalating the amount of porosity via incorporation of more than 0.25 wt% GO, the mechanical characteristics could be reduced (Paz *et al.*, 2017). The obtained results of PMMA-PCL/FA/GO-based BCs (Pahlevanzadeh *et al.*, 2018) showed that adding GO to PMMA-PCL/FA-based BCs enhances the mechanical properties due to a high amount of functional groups, including hydroxyl and carboxyl on the surface of GO. Moreover, the GO sheets have a large specific surface area besides its wrinkly surface, leading to a higher adhesion/interlock between GO and the polymer-based matrix (Pahlevanzadeh *et al.*, 2018; Gonçalves *et al.*, 2012; Soleymani Eil Bakhtiari *et al.*, 2020a). In another study by Phakatkar *et al.* (2020) that conducted on PMMA-Mg/HA-based BCs, the incorporation of both fillers can lock the deformation, thus enhancing the compressive strength of the nanocomposites. The findings consequently exhibited that the PMMA nanocomposite containing 7.5 wt% MgP nanosheets and 2.5 wt% HA nanofibers presented great compressive strength. Nevertheless, by escalating the amount of HA nanofibers from 5 to 7.5 wt% in the PMMA composite BC, the compressive strength diminished progressively. It appears that escalating the amount of HA nanofibers more than 2.5 wt% could possibly cause to the agglomeration hence decreasing the homogeneity of BC composite matrix that can eventually decrease the compressive strength by helping the

formation of voids and internal cavities (Phakatkar *et al.*, 2020; Singh *et al.*, 2008). In another study by Goto *et al.* (2005), bioactive PMMA-based BCs containing nTiO₂ particles were fabricated for use as bone substitutes. The results obtained from PMMA/silanized TiO₂-based BCs showed that adding 60 wt% silanized TiO₂ to PMMA-based BCs provides an equivalent compressive strength (Goto *et al.*, 2005). In other study by Slane *et al.* (2014), PMMA-based BCs were modified with MSNs and their mechanical, fatigue and absorption properties were investigated. In this perspective, Slane *et al.* (2014) depicted that greater MSNs amount leads to enhancement of the mechanical characteristics (flexural modulus, compressive strength and modulus). On the other hand, the flexural strength and fracture toughness diminished drastically with the escalating MSNs amount. MSNs strongly affected the fatigue characteristics, with significant detrimental effects when a high MSN amount was incorporated in the BC. These findings point out that MSN as used in this study, was not an efficient reinforcement phase utilizing in PMMA-based BC (Slane *et al.*, 2014). Russo *et al.* (2017) examined the mechanical characteristic of PMMA-based BCs encapsulated with AuNPs. Their finding demonstrated that the addition of AuNPs amplified the compressive modulus of BCs slightly. Especially by introducing 1 wt% of AuNPs, the compressive modulus for the nanocomposite BC was higher in comparison with that pure BC and other BC formulations. Their result likewise depicted that the addition of 0.25 wt% of AuNPs, on the other hand, appeared to improve the maximum stress of the BC, although a reduction was noticed by more escalating the amount of AuNPs. It was worth noting that less significant variations were observed between pure BC and nanocomposite BCs (Russo *et al.*, 2017). Before and after SBF incubation for 4 h, the compressive strengths of PMMA/PAAS_f-based BCs were assessed by Tang *et al.* (2017). The compressive strength of pure PMMA-based BC was around 90 MPa. The pure PMMA-based BC was not degraded in the SBF; consequently, the compressive strength stayed predominately unaffected after incubation in SBF. By escalating PAAS_f amount, the compressive strengths of PMMA/PAAS_f-based BCs prior to incubation in SBF diminished slowly because the strength of PAAS_f was lower compared with PMMA. Furthermore, in contrast to those prior to incubation, absorption of SBF and the expansion of the volume of the BCs containing PAAS_f after incubation in SBF for 4 h get through to saturation level, and the compressive strength of BCs diminished (Tang *et al.*, 2017). After incubation in SBF, the three-dimensional structure of PAAS_f shaped a hydrogel with a substantial water amount (Xue *et al.*, 2014). In this view, Tang *et al.* (2017) also indicated that with volume expansion of the BCs; the compressive strength of the BCs containing PAAS_f were significantly decreased (Tang *et al.*, 2017).

Effect of Different Reinforcements on Biological Properties

As mentioned above, traditional acrylic BCs could not regularly increase bone ingrowth. In order to enhance the biological behavior of the BCs, they should contain various types of reinforcements. The cellular response of PMMA-based BCs containing different reinforcements including HA, HA/CS, MWCNTs, CS, quaternized CS, CS/GO, CS/MWCNTs, TCP/CS, PCL/BAGH, calcium silicate, MC, PCL/FA/GO, MgP, silanized TiO₂, nano MgO, nano BaSO₄ and PAAS_f are tabulated in Table 3.

HA is one of the reinforcements that used in order to improve biological properties of PMMA-based BCs. In studies (Dalby *et al.*, 1999, 2001) adding HA to the PMMA-based BCs provide a more appropriate substrate for human osteoblast (HOB) cells, leading to an increase in cell proliferation and alkaline phosphatase (ALP) activity (Dalby *et al.*, 1999, 2001; Soleymani Eil Bakhtiari *et al.*, 2020b). In another study by Pino-Mínguez *et al.* (2015), biological results from PMMA/HA-based BCs indicated that at a concentration between 15% and 20% provided a favored condition for osteoblastic proliferation without altering their osteogenic capacity and lower toxicity than pure PMMA and composites with lower concentrations (Pino-Mínguez *et al.*, 2015). In other studies (Itokawa *et al.*, 2007; Sa *et al.*, 2017) PMMA/HA-based BCs were regarded as good candidates for cranial bone implants due to its good osteoconduction and biocompatibility (Itokawa *et al.*, 2007; Sa *et al.*, 2017). In another study (Kim *et al.*, 2004), the results of *in vitro* and animal studies of the PMMA-HA/CS-based BCs indicated that the proposed BCs have the potential for clinical applications as replacements for the pure commercial PMMA-based BCs (Kim *et al.*, 2004). In another study by Wang *et al.* (2019), *in vitro* study of PMMA/MWCNTs-based BCs represented that adding MWCNTs to the PMMA-based BCs improved cell adhesion and proliferation. Moreover, *in vivo* study indicated that new bone formation inside the BCs and the integration between the BCs and bone tissue were significantly enhanced with an increase in MWCNTs content within 12 weeks of post-surgery (Wang *et al.*, 2019; Soleymani Eil Bakhtiari *et al.*, 2020a,b). In another study by Ormsby *et al.* (2012), the obtained results of PMMA/MWCNTs-based BCs showed that adding MWCNTs to the PMMA-based BCs, caused to a better attachment and proliferation of MG-63 osteoblastic cells on the BCs (Ormsby *et al.*, 2012; Soleymani Eil Bakhtiari *et al.*, 2020a,b). In another study by Endogan *et al.* (2014), *in vivo* studies performed on PMMA/CS-based BCs confirmed appropriate bone-bonding ability and bioactivity of them (Endogan *et al.*, 2014). In other study by Tan *et al.* (2012), the cellular behavior of PMMA/quaternized CS-based BCs presented a higher stem cell proliferation, osteogenic differentiation, and osteogenesis-associated genes expression on their surfaces in comparison with the gentamicin-loaded PMMA-based BCs (Tan *et al.*, 2012). In another study by Valencia Zapata *et al.* (2019) the presence of CS and GO improved ALP activity in the PMMA-CS/GO-based BCs (Valencia Zapata *et al.*, 2019). In another study by Zapata *et al.* (2020) cell viability and cell attachment of PMMA-CS/GO-based BC examined, and their findings revealed that BC presents great cell response. In their *in vivo* study, both subdermal and bone parietal implantations in Wistar rats were evaluated. Modified PMMA-based BCs revealed a lack of immune reaction, as verified by a normal inflammatory response in Wistar rat subdermal implantation. The outcomes of the parietal bone implantation proved that the incorporation of CS and GO together permitted a near-complete healing bone-cement interface, as detected in the micrographic examination (Zapata *et al.*, 2020). In another study by Soleymani Eil Bakhtiari *et al.* (2020c) by adding 25 wt% CS/MWCNTs composite powder to PMMA-based BC, the activity of the osteocyte cells leads to the formation of the extracellular matrix (ECM), leading to an increase in the

Table 3 Cellular responses of PMMA-based composite BCs containing different types of reinforcements

Sample of BCs	Cellular assay	Cell type	Target tissue	Application	Reference
PMMA/17.5 wt% HA	Increasing in proliferation and ALP activity	Primary human osteoblast (HOB)-like cells	Bone	<i>In vitro</i>	(Dalby <i>et al.</i> , 1999; Soleymani Eil Bakhtiari <i>et al.</i> , 2020b)
PMMA/17.5 wt% HA	Increasing in expression of adhesion plaques, Higher cell proliferation and differentiation, Higher levels of ALP activity	Primary human osteoblast (HOB)-like cells	Bone	<i>In vitro</i>	(Dalby <i>et al.</i> , 2001)
PMMA/15 and 20 wt% HA	Better osteoblast response, with higher osteoblastic activity markers, Lower apoptosis markers	Human osteoblasts (cellular lineage ATTC Saos-2)	Bone	<i>In vitro</i>	(Pino-Minguez <i>et al.</i> , 2015)
PMMA/67 wt% HA	Good osteoconductivity and biocompatibility	—	Bone	<i>In vivo</i>	(Itokawa <i>et al.</i> , 2007)
PMMA/HA	Good osteoconductivity, Supporting direct bone-to cement contact	—	Bone	<i>In vivo</i>	(Sa <i>et al.</i> , 2017)
PMMA-50 wt% HA/10 wt% CS	Improvement in cell attachment and proliferation	Human osteoblast (HOB)-like cells, MG-63	Bone	<i>In vitro</i>	(Kim <i>et al.</i> , 2004)
PMMA-50 wt% HA/10 wt% CS	More biocompatible and osteoconductive than pure PMMA-based BC	—	Bone	<i>In vivo</i>	(Kim <i>et al.</i> , 2004)
PMMA/MWCNTs	Improvement in cell adhesion and proliferation. Promotion in osteogenic differentiation	Rat bone marrow-derived mesenchymal stem cells (rBMSCs)	Bone	<i>In vitro</i>	(Wang <i>et al.</i> , 2019; Soleymani Eil Bakhtiari <i>et al.</i> , 2020a,b)
PMMA/MWCNTs	New bone formation, Significant enhancement in the integration between the BC and bone tissue	—	Bone	<i>In vivo</i>	(Wang <i>et al.</i> , 2019)
PMMA/MWCNTs	Successfully adherence and proliferation on the surfaces of all PMMA/MWCNTs-based BCs	Osteoblast-like MG-63 cells	Bone	<i>In vitro</i>	(Ormsby <i>et al.</i> , 2012; Soleymani Eil Bakhtiari <i>et al.</i> , 2020a,b)
PMMA/CS (0.05 g/g) (Particle size range of PMMA: 50–150 μ m)	Enhancement in <i>in vivo</i> osteogenic activity	—	Bone	<i>In vivo</i>	(Endogan <i>et al.</i> , 2014)
PMMA/Quaternized CS	Improvement in stem cell proliferation, Osteogenic differentiation, Expressing osteogenesis-associated genes on the surface of the BCs	Human mesenchymal stem cells (hMSCs)	Bone	<i>In vitro</i>	(Tan <i>et al.</i> , 2012)
PMMA-15 wt% CS and 0.3 wt% GO/15 wt% CS	Enhancing ALP activity, Inducing osteoblastic activity, Increasing osteogenic activity, Supporting good cell viability of HOB	Human osteoblasts (HOB)	Bone	<i>In vitro</i>	(Valencia Zapata <i>et al.</i> , 2019)
PMMA-0.3 wt%GO/15 wt% CS	Higher extracellular matrix (ECM) formation	Human osteoblasts (HOB) cells (ECACC 06090739)	Bone	<i>In vitro</i>	(Zapata <i>et al.</i> , 2020)
PMMA-0.3 wt%GO/15 wt% CS	Enhancement in biomineralization, Greater integration with bone, Improvement in biocompatibility	—	Bone	<i>In vivo</i> (subdermal and bone parietal implantations)	(Zapata <i>et al.</i> , 2020)
PMMA-25 wt% (CS/MWCNTs)	The activity of the osteocyte cells led to the formation of the ECM	Human osteosarcoma cell line MG-63	Bone	<i>In vitro</i>	(Soleymani Eil Bakhtiari <i>et al.</i> , 2020 a,b,c)
PMMA-25 wt% (CS/GO)	Improvement in cell viability, growth, and cell adhesion	Osteoblast-like cell line (MG-63)	Bone	<i>In vitro</i>	(Tavakoli <i>et al.</i> , 2020a; Soleymani Eil Bakhtiari <i>et al.</i> , 2020 a,b)
PMMA/TCP/CS	Non-cytotoxic	Mouse fibroblast cell line (L929)	Bone	<i>In vitro</i>	(Fang <i>et al.</i> , 2019)
PMMA/TCP/CS	More osteoconductivity	—	Bone	<i>In vivo</i>	(Fang <i>et al.</i> , 2019)
PMMA-PCL/BAGH	Improvement in the viability of MG-63 osteoblasts, Higher cell attachment and spreading	MG-63	Bone	<i>In vitro</i>	(Pahlevanzadeh <i>et al.</i> , 2019b)
PMMA/Calcium Silicate	Well grow ability,Excellent proliferation viability	Human bone marrow stromal cells (HBMSCs)	Bone	<i>In vitro</i>	(Sun <i>et al.</i> , 2019)
PMMA/Calcium Silicate	Remarkable degradation, Significant new bone formation	—	—	<i>In vivo</i>	(Sun <i>et al.</i> , 2019)

Table 3 Continued

Sample of BCs	Cellular assay	Cell type	Target tissue	Application	Reference
PMMA/MC	Excellent bone tissue compatibility	L929 mouse connective tissue cells	Bone	<i>In vitro</i>	(Li <i>et al.</i> , 2015)
PMMA/MC	Higher bone-cement interface crosslinking than control BC after 6 months implantation in the femur of rabbits.	–	Bone	<i>In vivo</i>	(Li <i>et al.</i> , 2015)
PMMA-PCL/FA/GO	High cells viability	MG-63 osteoblast cells	Bone	<i>In vitro</i>	(Pahlevanzadeh <i>et al.</i> , 2018; Soleymani Eil Bakhtiari <i>et al.</i> , 2020a)
PMMA/10 wt% HA nanofiber	More cells survived than other BCs	Fibroblasts cells	Bone	<i>In vitro</i>	(Phakatkar <i>et al.</i> , 2020)
PMMA-10 wt% MgP nanosheet	Highest amount of cytocompatibility	Fibroblasts cells	Bone	<i>In vitro</i>	(Phakatkar <i>et al.</i> , 2020)
PMMA/60 wt% silanized TiO ₂	Better osteoconductivity than other BCs	–	Bone	<i>In vivo</i>	(Goto <i>et al.</i> , 2005)
PMMA/nano MgO	Enhancement in osteoblast adhesion	Human osteoblasts (CRL-11372)	Bone	<i>In vitro</i>	(Ricker <i>et al.</i> , 2008)
PMMA/nano BaSO ₄	Enhancement in osteoblast adhesion	Human osteoblasts (CRL-11372)	Bone	<i>In vitro</i>	(Ricker <i>et al.</i> , 2008)
PMMA/MC	Cells can start proliferation and differentiation earlier a few days on PMMA/MC-based BCs than that on PMMA-based BC	Human bone marrow-derived stem cells	Bone	<i>In vitro</i>	(Wu <i>et al.</i> , 2016)
PMMA/PAAS ₁	No significant difference existed between composite BCs and PMMA-based BC in cytotoxicity test	Fibroblast cells	Bone	<i>In vitro</i>	(Tang <i>et al.</i> , 2017)

possibility of cellular differentiation (Soleymani Eil Bakhtiari *et al.*, 2020a,b,c). In another study by Tavakoli *et al.* (2020a) the results obtained from the cell culture study of MG-63 confirmed the improvement of cell viability, growth, and cell attachment on the 25 wt% of PMMA-CS/GO-based composite BC (Tavakoli *et al.*, 2020a; Soleymani Eil Bakhtiari *et al.*, 2020a,b). In another study (Fang *et al.*, 2019), cell proliferation tests of the PMMA-TCP/CS-based BCs confirmed the non-cytotoxicity of them. Moreover, *in vivo* studies revealed that they are more osteoconductive than pure PMMA-based BC (Fang *et al.*, 2019). In another study by Pahlevanzadeh *et al.* (2019b) 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium-bromide (MTT) assay demonstrated an enhanced cellular activity of the BC in combination with BAGH. The osteoblast adhesion and spreading ability on the BC containing BAGH were significantly higher than the BC without BAGH in the same duration of cell culture, and ALP activity on the BC containing BAGH was also higher than the BC without BAGH on the 3rd and 7th days (Pahlevanzadeh *et al.*, 2019b). In another study by (Sun *et al.*, 2019) *in vitro* study of the PMMA/calcium silicate hybrid BCs revealed that human bone marrow stromal cells (HBMSCs) were able to grow well while presented excellent cell proliferation and viability. Moreover, *in vivo* study in goat vertebral body defect models demonstrated well biodegradability and significant promotion of new bone formation in defects within 6 months of post-injection (Sun *et al.*, 2019). In this perspective, Wekwejt *et al.* (2020) disclose that reinforced BCs with cellulose, CS, Mg, PDO, or TCP presented more apatite formation ability, which is connected with time-varying porosity. In turn, this impacts their osteoconductivity and plays a role in the effective release of active compounds that improve specimens' antibacterial efficacy. Additives, on the other hand, might decrease their cell viability, particularly at a greater concentration (Wekwejt *et al.*, 2020). In another study by Li *et al.* (2015) the biological properties of PMMA/MC-based BCs revealed that after adding MC to PMMA-based BCs, these BCs were biologically safe in cytotoxicity regarding blood compatibility, the local reaction after implantation, acute systemic toxicity, and chronic liver and kidney toxicity. Moreover, the BC interface crosslinking was significantly higher after implantation in the distal femur of rabbits. A comparison between gene expression of the PMMA/MC-based BCs and control PMMA-based BC groups also revealed that PMMA/MC-based BCs might improve osteogenic bioactivity (Li *et al.*, 2015). In other study by (Pahlevanzadeh *et al.*, 2018) the cytotoxicity test results related to the PMMA-PCL/FA/GO-based BCs represented that MG-63 osteoblast cell viability increased as the FA and GO contents added into the PMMA-PCL polymer BCs (Pahlevanzadeh *et al.*, 2018; Soleymani Eil Bakhtiari *et al.*, 2020a). In another study by Phakatkar *et al.* (2020) cellular obtained results from PMMA-MgP/HA-based BCs showed that the synthesized nanocomposite possesses excellent bioactivity and cytocompatibility potentially (Phakatkar *et al.*, 2020). In another study (Goto *et al.*, 2005), animal experiments of PMMA/60 wt% silanized TiO₂-based BC presented a significantly higher osteoconduction potential in comparison with the other BCs at each time interval (Goto *et al.*, 2005). In another study by Ricker *et al.* (2008) adding nanoparticles of MgO and BaSO₄ to PMMA-based BCs

led to an increase in osteoblast attachment on PMMA-based BCs (Ricker *et al.*, 2008). In another study conducted by Wu *et al.* (2016) adding MC to PMMA-based BCs indicated that osteogenic differentiation on MC incorporated in PMMA-based BCs was more than two times higher than PMMA-based BCs during 21 days of cell culture study (Wu *et al.*, 2016). In a study by Tang *et al.* (2017) cytotoxicity was compared between PMMA-based BC and PMMA/PAAS_F-based BCs, and their result indicated that their cytotoxicity did not differ considerably by the addition of PAAS_F (Tang *et al.*, 2017).

Conclusions and Future Work

PMMA, as a biocompatible polymer, has wide applications in medicine, especially in BCs. Because of some inappropriate properties of PMMA-based BCs such as thermogenesis during polymerization process, weak mechanical properties and lack of bioactivity, different methods developed to address these issues. Using ceramics, polymers, and composites as reinforcement agents in PMMA-based BCs is one of the common methods to enhance their physical, mechanical, and biological properties. Considering the reviewed studies on the BCs, using different reinforcement agents could create various advantages for PMMA-based BCs. Furthermore, interestingly, the addition of HA, GC, HA/CS, MWCNTs, *f*-MWCNTs, CS, quaternized CS, GO, CS/MWCNTs, CS/GO, CS- β -TCP, TCP, PCL/BAGH, cellulose, PDO, and PAAS_F into PMMA-based BCs have been proved to decrease maximum temperature and increase setting time. Moreover, the addition of HA in a smaller extent into PMMA/HA-based composite BCs increases mechanical properties since it acts as load-bearing. In particular, the superior mechanical properties of PMMA/carbon-based composite BCs can be attained with encapsulation of a specific amount of CBNs into the BC owing arresting/retarding crack propagation in the BCs structure for orthopedics applications. The studies have exhibited that BCs encapsulated with HA, CS, quaternized CS, CS/MWCNTs, PCL/BAGH, calcium silicate, PCL/FA/GO, HA nanofiber, MgP nanosheet, nano MgO, nano BaSO₄ are shown high cytocompatibility *in vitro*. In light of this, PMMA-based BCs containing HA/CS, CS/GO, TCP/CS, calcium silicate, MC, silanized TiO₂ induce bone formation *in vivo*. The continuous study progresses in PMMA-based BCs and is essential to the accomplishment of touchable and clinically pertinent outcomes in the treatment of bone defects.

Drug Delivery

Drug delivery can be described as “the methods to administer the pharmaceutical ingredients so as to achieve therapeutic effects in humans or animals” (Bhowmik *et al.*, 2012; Tiwari *et al.*, 2012). Oral and parenteral routes are frequently employed for drug administration but have several limitations such as oral route is associated with high drug susceptibility to enzymes in gastrointestinal tract (Liu *et al.*, 2003), first pass effect, poor absorption of peptides and proteins, and poor patient compliance for those who are unable to take any oral medication (Rathbone *et al.*, 1994). Similarly, parenteral route has several limitations as being painful, lack of self administration, local injury, thrombus formation, and hypersensitivity reactions (Bruce and Wong, 2001). In literature, it is suggested that skin, one of the largest organs of body may be used as an alternative route for several drugs either by transdermal drug delivery or topically for localize pharmacological response (Tiwari *et al.*, 2012). Both systems are suitable for patients who are unable to take any oral medication, thus enhances patient compliance (Mazzitelli *et al.*, 2013) and provides control drug release for prolong period (Grampurohit *et al.*, 2011).

Drug Delivery Through Skin

Being one of the largest organs of body, skin occupies an area of about two meter square (Hopewell, 1990). Skin has three layered (epidermis, dermis and hypodermis) complex structure (Metcalf and Ferguson, 2007), which acts as a main barrier and separates the underlying tissues from outer environment (Kamoun *et al.*, 2017), regulates temperature, prevents the electrolytes and water loss, and impedes entry of toxic chemicals, allergens, microbes and irritants. Skin can be used for both transdermal delivery (systemic effect) and topical delivery (local effect) of several drugs (Prausnitz and Langer, 2008).

Wound

Wound may be defined as any disruption, break or disorder in normal skin structure and functions (Boateng *et al.*, 2008). A wound primarily may result from any physical, thermal or chemical skin damage while secondary cause include several diseases (carcinoma, diabetes or ulcers) and any surgical intervention. Depending upon the type of skin tissues and cells that undergo disruption, wounds may range from superficial to full thickened wound as shown in Fig. 1.

When outermost layer is affected by temperature, extreme pressure, any chemical or cut, it is a superficial wound; when epidermis and dermis layer along with hair follicles and blood vessels are affected then it is partially thickened wound; while any injury to hypodermal fats or deeper tissues results in full thickened wounds (Sarheed *et al.*, 2016; Boateng *et al.*, 2008). Wounds can also be classified as acute and chronic wounds depending upon their healing time. Acute wounds requires limited time to heal, and no serious complications are involved. Chronic wounds require prolonged healing time and are characterized by prolonged inflammation, presence of microbial pathogens, persistent infection and impaired healing (Boateng *et al.*, 2008).

Wound healing

A biological process that follows the general phenomenon of tissue regeneration and growth is referred as wound healing (Reinke and Sorg, 2012). Healing process is comprised of following stages; hemostasis, inflammation, proliferation, and remodeling as depicted in Fig. 2 (Sarheed *et al.*, 2016).

Fig. 1 Classification of wounds. Adapted from Da, L.-C., Huang, Y.-Z., Xie, H.-Q., 2017. Progress in development of bioderived materials for dermal wound healing. *Regenerative Biomaterials* 4, 325–334.

Fig. 2 Various stages of wound healing process. Reproduced from Mellott, A.J., Zamierowski, D.S., Andrews, B.T., 2016. Negative pressure wound therapy in maxillofacial applications. *Dentistry Journal* 4, 30.

(1) *Hemostasis*

Hemostasis is characterized by bleeding, immediately after an injury or trauma and involves flushing of antigens and bacteria from wound site. Released cytokines and inflammatory mediators causing platelet aggregation (Boateng *et al.*, 2008).

(2) *Inflammation*

This stage starts simultaneously with hemostatic stage and lasts for about 72 h. It is characterized by release of prostaglandins and histamine from mast cells, monocytes migrate to wound area causing edema and inflammation (Sarheed *et al.*, 2016).

(3) *Proliferative phase*

Proliferative phase is characterized by production of growth factors, which initiate the process of angiogenesis and epithelial thickening with collagen deposition (Boateng *et al.*, 2008).

(4) *Remodeling*

Remodeling is characterized by re-epithelialization, connective tissue formation, wound contraction, and wound closure.

Wound dressings

Wound dressings not only covers the wound but also helps in regeneration of epidermal tissues during healing process (Adamian *et al.*, 2004). These dressings act as physical barrier and protect the wounds from invading microorganisms (Mogoşanu and Grumezescu, 2014). Effective wound dressing maintains the moisture at wound area which helps to transport the keratinocytes, growth factors and enzymes (Moura *et al.*, 2013) to promote healing (Dumville *et al.*, 2013).

In ancient periods, wound dressings were prepared from crude plants, animal fats and honey which have antimicrobial properties (Inngjerdingen *et al.*, 2004). However, direct application of crude plant was harmful, as it would contain chemicals or microorganisms, which may cause infection. So, this recognition led to development of dressings having effective antimicrobial moiety and enzymatic agents (Thomas, 2000). Until 1962, it was thought that wound healing would be faster if kept dried. This concept was changed by work of "Winter", who, for the first time, designed the moist wound films and revealed that healing is faster in wet environment as it helps in epithelialization and faster cell proliferation (Kamoun *et al.*, 2017).

Requirements for wound dressings

Ideal dressings must have ability to keep moist environment at wound surface, remove exudates, provide protection from microbes and promote healing (Kamoun *et al.*, 2017). Ideal dressings must provide mechanical protection, thermal insulation and oxygen exchange and are compatible with biological systems (Altioek *et al.*, 2010). Furthermore, it must be non-allergenic, biodegradable, non-toxic and cost effective (Kokabi *et al.*, 2007).

Classification of wound dressings

Wound dressings can be classified in several ways; depending on their functions (Queen *et al.*, 2004), on the basis of material used for their production (Purna and Babu, 2000), and on their physical form as shown in Fig. 3. Most commonly, dressings are classified as traditional and modern dressings (Thomas, 2000).

Fig. 3 Classification of wound dressings.

Fig. 4 Structure of thin hydrogel films.

Traditional dressings

Traditional dressings include bandages, cotton wools, and gauzes. These dressings, being easy to fabricate, easy to use and low cost, were frequently used till 1990s (Edwards *et al.*, 2001). These dressings are dry in nature and do not maintain moisture at wound site, thus, leading to dehydration which promotes microbial growth at wound site (Van Rijswijk, 2006).

Modern dressings

These dressings are most preferred ones as they keep the wound site moist, which helps in wound repairing and healing. Modern dressings are further classified as biological dressings (comprised of biomaterials) and artificial dressings (composed of non-biological or synthetic materials/polymers) (Kamoun *et al.*, 2017).

Hydrogel Films

Generally the term “gel” refers to a viscoelastic deformable network in continuous medium that is either gas or liquid (Mateescu *et al.*, 2012). When continuous phase is gas then system is known as aerogel, and in case of liquid, system is generally termed as lyogel, and for water it is referred as hydrogel (Künzler, 2002). Hydrogel films are defined as “three dimensional crosslinked thin films of hydrophilic polymers which have tendency to absorb large amount of water without solubilizing or losing integrity due to strong junctions between its segments” (Ahmed, 2015) or can be defined as “soft, flexible, water swollen, three dimensional crosslinked macromolecular network of hydrophilic polymers” (Ye and Loh, 2013). Functional groups of hydrophilic polymers provide the capability to absorb water, while crosslinks between the polymeric chains prevents their disintegration in desired media.

In hydrogel films, polymers are crosslinked via physical or chemical interactions (Fig. 4); physical interactions are mechanically weak, reversible and may be effected by environmental factors like temperature, ionic strength and pH. On the other hand, chemical interactions are more stable and strong, but chemical agents may be toxic (Uliniuc *et al.*, 2013).

Properties and applications of hydrogel films

- (1) Hydrogel films have gained considerable attention due to their unique properties like ability to retain high water content, high aqueous stability, biocompatibility with biological system, softness, elasticity and can load variety of agents in high enough concentration and release them in controlled manner (Mali *et al.*, 2017).

Fig. 5 Applications of hydrogel films.

- (2) Hydrogels have ability to mimic the physical, chemical, electrical, and biological properties of biological tissues (Gaharwar *et al.*, 2014).
- (3) Hydrogel films have remarkable mechanical, optical, and surface properties which make it a promising material for diverse applications (Seliktar, 2012).
- (4) Hydrogels have ability to hold up to 40 folds of more water as compared to their initial dry weight (Gaharwar *et al.*, 2014).
- (5) One of the remarkable properties of hydrogel films is their porous nature, which allows high drug loading and high local concentration at targeted site (Zhao *et al.*, 2015).
- (6) Hydrogel films have been proposed for several biotechnological and biomedical applications like wound healing (Thu *et al.*, 2012), tissue engineering, cell adhesion (Hoare and Kohane, 2008), cosmetics, and food industry (Fig. 5; Ejaz *et al.*, 2018).
- (7) Biodegradability of hydrogels is an essential factor for biomedical applications.
- (8) Hydrogel films have also tailored the vast applications in immune-modulation, stem cell engineering, cellular and molecular therapies, in vitro diagnostics and anti-cancer research (Fig. 5; Gaharwar *et al.*, 2014).

Composite Hydrogel Films

Mostly, one polymer is exploited for preparation of hydrogels network but it lacks biological and mechanical properties essential for biomedical application. As single polymeric network, structure is too flexible that leads to premature drug release at targeted site. To overcome these problems, multiple entities are incorporated into hydrogel system to formulate a composite material (Gaharwar *et al.*, 2014).

Composite hydrogel films can be defined as “the systems which contain two or more than two constituent materials with different physicochemical properties, where individual constituent materials remain distinct and separate but impart different and better characteristics to the final composite system” (Ye and Loh, 2013). Main purpose of fabrication of composite films is strength enhancement and reinforcement. Recently, composite hydrogel films have gained much attention in drug delivery, biomedical applications, medical devices, cosmetics as well as in food industry due to their reliability and high stability (Roy and Rhim, 2020; Alavi *et al.*, 2019; Ejaz *et al.*, 2018; Liu *et al.*, 2008).

Synthesis of Hydrogel Films

Main principle for synthesis of hydrogel films is crosslinking of polymeric chains, after which films show viscoelastic or pure elastic behavior. Crosslinking is achieved by either addition of crosslinking agents, through chemical modification or by exposure of high energy radiations. These methods of crosslinking are categorized in two main categories i.e., physical crosslinking and chemical crosslinking. Chemically crosslinked films are more stable as compared to physically crosslinked films but chemical crosslinking agents are toxic. Therefore, both methods have their own benefits as well as drawbacks discussed under respective details. Different methods involved in preparation of films are shown in Fig. 6.

Fig. 6 Various method employed to develop hydrogel films.

Fig. 7 Physical crosslinking in polymers (a) ionic interaction (b) complex coacervation.

Physical crosslinking

Ionic interactions

Ionic crosslinking is carried out by addition of di or tri valent counter ions in polymeric solution under specific conditions i.e., room temperature and at physiological pH. For example, polysaccharides are crosslinked via calcium ions (counter ion) (Pereira *et al.*, 2013b) as shown in Fig. 7(a). This method provides mechanically stable gels with uniform structure which are easily degraded in physiological solution (Ali and Ahmed, 2018). Interestingly, these gels can be easily destabilized by extracting the counter ions through chelating agents (Ullah *et al.*, 2015). However, in this method it is difficult to control the gelation rate as it increases with increasing the concentration of polymer and temperature.

Hydrogen bonding

This method is utilized for polymers that have carboxyl groups, which undergo protonation leading to hydrogen bonding and show pH dependent swelling (Akhtar *et al.*, 2016). For this purpose, polymeric solution is dispersed into acidic solution (0.1 M HCl) where sodium ions are replaced by hydrogen ions leading to hydrogen bonding and formation of elastic hydrogel (Takigami *et al.*, 2007).

Freeze thaw method

Freeze thaw method is one of the promising methods for hydrogel films synthesis especially for polysaccharide based polymers, where strong, highly porous, interconnected, rubbery and elastic gels are produced (Varaprasad *et al.*, 2017). In this method polymer solution is frozen at low temperature (-20°C to -80°C) followed by melting at room temperature (Ali and Ahmed, 2018). Gel formation is attributed to formation of microcrystals of polymers that act as crosslinking sites in network. Properties of finally formed gel depends upon the molecular weight of polymer, concentration of polymer in water, temperature, number and duration of freezing cycles, pH and rate of thawing. Mechanical properties of films can be enhanced by increasing the freeze thaw cycles and by lowering the temperature (Ullah *et al.*, 2015). Ahmed *et al.*, used this method for preparation of PVA-PEG based films for wound healing (Ahmed *et al.*, 2018).

Complex coacervation

Principle of complex coacervation is the usage of oppositely charged polymers i.e., polycationic and polyanionic polymers which when aggregate together, form a complex as shown in [Fig. 7\(b\)](#), depending upon pH and polymer concentration ([Ali and Ahmed, 2018](#)).

Chemical crosslinking

Although, physical crosslinking method has the advantage of preparing gel matrix without addition of any crosslinking agent but these physical junctions do not have enough mechanical strength while chemically crosslinked films are mechanically strong. Chemical crosslinking involves following methods.

Addition reaction/by chemical agents

This method involves the addition of chemicals such as glutaraldehyde, PEG, glyoxal, epichlorohydrin, and polyaldehydes etc. which form covalent linkages between polymers. These covalent bonds are formed by reaction of functional groups of polymers (OH, COOH, and NH₂) with complementary reactivity such as an amine-carboxylic acid or an isocyanate-OH/NH₂ reaction ([Varaprasad et al., 2017](#)).

High energy radiation method

This method is also named as “radiation grafting” where high-energy radiations such as gamma radiations or electron beam are used to initiate the free radical polymerization reaction. Mostly unsaturated compounds are polymerized by this method where hydrophilic polymers on exposure to gamma radiations/electron beam are derivatized through polymerizable groups and form radicals on polymeric chains via homolytic scission ([Zhao et al., 2003](#); [Zhai et al., 2002](#)). These radiations assist the water molecules to form the hydroxyl group, which attack polymer chains and form micro-radicals. Aggregation of different micro-radicals of different polymer chains lead to formation of covalent bonds resulting in crosslinked structure. Although, this method does not use any toxic chemical agents as well as whole process is carried out at room temperature and physiological pH. However, this method yields non-biodegradable gels ([Varaprasad et al., 2017](#)).

Free radical polymerization technique

Hydrogel films are efficiently crosslinked by this method where low molecular weight monomers are crosslinked in presence of crosslinking agent through polymerization technique. Free radical initiators such as potassium or ammonium persulfate or benzoyl peroxide are used to initiate the process of polymerization, which results in rapid gel formation under mild temperature conditions.

Condensation reaction

Polyamides and polyesters are synthesized by condensation reaction method, where reaction takes place among NH₂ or OH groups with COOH respectively. For crosslinking of hydrophilic polymers through condensation reaction, the most efficient reagent is N,N-(3-dimethylaminopropyl)-N-ethyl carbodiimide (EDC) having amide group ([Akhtar et al., 2016](#)). PVA and gelatin hydrogels have been synthesized by using EDC ([Ray et al., 2010](#); [Kuijpers et al., 2000](#)).

Why Hydrogel Films as Wound Dressings?

Hydrogel films can act as favorable dressings for wound healing due to their intrinsic properties of absorbing and retaining exudates at wound site, which promotes the fibroblast formation, cell proliferation and keratinocytes migration. Highly porous nature of hydrogel films allows the transportation of bioactive compounds such as antibiotics and other pharmaceutical ingredients at wound site. These bioactive compounds are entrapped in film matrix during gelling process and are exchanged with exudate, when film meets wound surface. Tight mesh size of film protects the wound from microbial infection and high water content of hydrogel films provides the required elasticity, flexibility and tissue like structure ([Kamoun et al., 2017](#)).

Composite Hydrogel Films as Wound Dressing*Composite films containing natural polymers*

Interest towards the use of natural polymers has increased specially in biomedical and regenerative field due to their tissue repairing and skin regeneration properties ([Huang and Fu, 2010](#)). Furthermore, natural polymers provide the advantage of being biodegradable and biocompatible with biological system. Vast variety of natural polymers are utilized for fabrication of composite hydrogel films for wound healing. In forthcoming sections, we will discuss most important polymers with relevant examples and studies carried out by various eminent research groups.

(a) Polysaccharides

Polysaccharides have excellent properties, which make this group one of the widely used polymeric group in biomedical field. These include high water solubility, swellability, non-toxicity, biodegradability, susceptibility to enzymatic digestion in body as well as high tissue compatibility and some of them are helpful to enhance healing process. Thus make it potential candidate for biomedical applications such as skin regeneration, tissue engineering and wound management ([Varaprasad et al., 2017](#)).

Fig. 8 (a) Self-healing capability of curcumin entrapped gelatin/iBC hydrogel films was assessed by “scratch and heal” test which shows the iBC contributes in healing of damaged film by developing ionically interlocked structure in the presence of a buffer solution. (b) Wound healing assay of on NIH-3 T3 fibroblast cells after treatment with pure ionically modified gelatin hydrogel film (control) and drug-loaded (G1 and G2 contains 7% and 12% curcumin respectively) ionically modified gelatin hydrogel film. Reproduced from Khamrai, M., Banerjee, S.L., Paul, S., Samanta, S., Kundu, P.P., 2019. Curcumin entrapped gelatin/ionically modified bacterial cellulose based self-healable hydrogel film: An eco-friendly sustainable synthesis method of wound healing patch. *International Journal of Biological Macromolecules* 122, 940–953, with permission from Elsevier.

i. Cellulose

Cellulose is a hydrophilic polysaccharide biomaterial with excellent properties such as biocompatibility, oxygen and nutrients permeability, high porosity etc. Cellulose itself have no antibacterial property (Kabir *et al.*, 2018) so, its hydrogel film dressing must contain other bactericidal agents. Cellulose based dressings are widely used but cause maceration of wound and pain during removal. These drawbacks can be overcome by combing it with other polymers or using hydrogels (Pinho and Soares, 2018). To overcome the said drawbacks, cellulose and its derivatives based composite hydrogel films have been fabricated in combination with other natural polymers. For e.g., bacterial cellulose from *Gluconacetobacter xylinus* was grafted with cationic and anionic segments to get ionically modified self-assembled bacterial cellulose (iBC) and later blended with gelatin to develop hydrogel films having inherent self-healing capability as shown in Fig. 8. Here, gelatin is caged in iBC and thus provides mechanical strength to films. Furthermore, these films were loaded with curcumin, which showed superior antibacterial and wound healing properties as compared to blank films. This difference is due to the presence of curcumin, which have antioxidant and antibacterial properties, and promotes cell proliferation and migration (Khamrai *et al.*, 2019).

In another study, sodium carboxymethyl cellulose/hydroxypropyl methylcellulose was crosslinked with citric acid and incorporated with various concentrations of grapefruit seed extract. Thermal and mechanical properties of films varied in grapefruit seed extract films. Furthermore, it was observed that addition of grapefruit seed leads to development of nanoparticles. Authors found that sodium carboxymethyl cellulose facilitates the formation of micelles while glycerides the main component of grape fruit seed extract is encapsulated in the core. These composite films show excellent antibacterial properties due to stable nanoparticles (– 55.26 mV) of grape fruit seed extract. Thus, these films loaded with natural extract can be used in wound healing and other biomedical applications (Koneru *et al.*, 2020). Work of these authors has proven the competency of cellulose based composite hydrogel films as a therapeutic substitute to previous cellulose based dressing, and furthermore, they are easily tuned to achieve specific objectives and deliver the therapeutic moiety at desired area.

ii. Alginate

Alginate is a linear polysaccharide, which is extensively used in wound dressings due to its hemostatic properties (Mogoșanu and Grumezescu, 2014), biocompatibility, non-toxicity, non-immunogenicity, affordability, and high fluid absorption capacity. However, alginate is reported to have poor mechanical properties, which limits its applications. These drawbacks can be overcome by (a) combining it with other suitable polymers to enhance the mechanical properties and modify their release and degradation pattern, (b) secondly, one can enhance its mechanical strength by crosslinking it to form hydrogel. On reviewing literature, we found several authors have developed composite alginate based hydrogel dressings for wound management. For e.g., alginate and pectin based composite hydrogel films were loaded with simvastatin. Here, crosslinking with calcium ions improved the mechanical profile and wound fluid uptake capacity as compared to non-crosslinked films. Non-crosslinked films

Fig. 9 Epithelialization score of various alginate/chitosan formulation having different concentration of vitamin E. Films with 400 IU of vitamin E responded better than one containing lower or higher concentration of vitamin E. Here, error bar indicated SD ($n = 6$), * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$. Reprinted from Ehterami, A., Salehi, M., Farzamfar, S., *et al.*, 2019. Chitosan/alginate hydrogels containing Alpha-tocopherol for wound healing in rat model. *Journal of Drug Delivery Science and Technology* 51, 204–213, with permission of Elsevier.

released the drug quickly, while crosslinked films released simvastatin in controlled manner and depends on crosslinking density of films. Here, slow and sustained simvastatin delivery, together with higher integrity of the hydrogel dressing is expected to improve wound healing by increasing the duration of drug release and healing process in diabetic wounds (Rezvanian *et al.*, 2017). Although statins are primarily used to lower bad cholesterol in body, but several studies suggest topical use of statins particularly simvastatin can stimulate wound healing as it promotes angiogenesis, lymph angiogenesis, microvascular function, boost immunological response, reduces oxidative stress and infections (Raposo *et al.*, 2016). In another study, alginate was blended with different concentration of Aloe vera (5%, 15% and 25%). Aloe vera had positive influence on the transparency of the films i.e., in dry as well as wet state. Moreover, water absorption capacity of films also increased with contents of Aloe vera. These films were innovative and unique in a sense that both ingredients used for film development also contributed to therapeutic efficacy. For instance, calcium alginate is hemostatic while therapeutic properties of Aloe vera include antibacterial, anti-inflammatory, anti-septic, and fibroblast proliferation activities. So, alginate/Aloe vera hydrogel films can be used as effective wound dressing in dry and exuding wounds (Pereira *et al.*, 2013a).

Alginate/chitosan hydrogel dressing were loaded with various concentrations of α -tocopherol (200–1600 IU) and assessed their efficacy in full-thickness excisional wound model in rats. In this study, researcher combined the two polymers having tissue engineering properties with α -tocopherol, which maintains cell integrity, modulate expression of connective tissue growth factors, and protects wounds against methicillin resistant *S. aureus*. Alginate/chitosan/400 IU α -tocopherol was effective dressings, which showed superior re-epithelization (Fig. 9), hair follicle formation and angiogenesis. This is attributed to antioxidant activity of α -tocopherol that provides protection to cells from oxidative damage and also acts as an important inhibitor of lipid peroxidation and anti-inflammatory agent (Ehterami *et al.*, 2019). At higher doses, wound healing was delayed due to adverse effects of vitamin E as reported previously (Brigelius-Flohé, 2007; Kappus and Diplock, 1992).

Similarly, alginate and chitosan were partially crosslinked with calcium chloride and sodium tripolyphosphate, respectively, and followed by interpolymer complexation. This formulation exhibited 4343.4% swelling, compared to 1612.56% by commercial alginate-based wound dressing (Mndlovu *et al.*, 2019) and thus can serve as potential wound dressings.

iii. Chitosan

Chitosan, a linear polysaccharide, has been revealed as biomaterial for wound management due to its antimicrobial and healing activities. Chitosan is believed to promote the cell migration, fibroblast formation, and cytokines production (Fan *et al.*, 2016). Composite films of chitosan along with other natural polymers have been documented in literature with well-known wound healing potential. Mupirocin loaded chitosan films with or without Aloe vera and sodium alginate and their combination was evaluated for wound healing potential by using rat models. They developed films with and without glutaraldehyde and presence of crosslinker decreased the bioadhesion and swelling. Results showed that the highest wound contraction (98%) was observed with drug loaded chitosan/sodium alginate/Aloe vera composite films on 12th day with superior mechanical properties and thus deemed as effective dressings for all types of wounds (Saleem, 2012). Another group of researcher reported a similar work but they designed the hydrogel films with similar combination i.e., chitosan, sodium alginate and mupirocin but they used carbapol instead of Aloe vera, a biomaterial with wound healing properties. These dressings showed improved mupirocin release, bioadhesion and maximum healing on 10th day in excisional rat model. Histogram revealed fast epidermal regeneration, new blood vessel formation, and granulation when compared with commercial product as shown in Fig. 10 (Okur *et al.*, 2019).

Fig. 10 (a) Histological scores of angiogenesis, granulation tissue thickness, and epidermal/dermal regeneration of untreated (UG), Bactroban® (BG), blank (FG), and mupirocin film (MG) treated groups. (b) Histopathological images of bactroban® and mupirocin film treated groups on 10th day of study after Hemotoxylen and eosin staining, showing better healing of wounds treated with mupirocin film. An alternative approach to wound healing field; new composite films from natural polymers for mupirocin dermal delivery. Saudi Pharmaceutical Journal 27, 738–752, with permission of Elsevier.

(b) Proteins and peptides

Several proteins of natural origin such as soya protein, collagen, gelatin and fibrin have applications in wound and burn healing as they stimulate the healing cascade by fibroblast formation, tissue regeneration, and cell proliferation (Mogoşanu and Grumezescu, 2014). For wound healing, numerous studies have been conducted by using natural proteins such as; composite films of soya protein and sago starch were prepared as wound dressings and evaluated in full-thickened wound models in rats. Researcher observed the complete wound closure at 20th day and normal skin like histology in histopathological studies. They also assesses various biochemical parameter like collagen, uronic acid and hexosamine. Higher level of these three parameters indicated the faster wound healing in groups treated with these composite films (Ramnath *et al.*, 2012).

Gelatin is a biopolymer derived from collagen and have numerous applications such as wound dressings, mucoadhesive patches, and other absorbent pads (Roy and Rhim, 2020; Türe, 2019; Fernandes *et al.*, 2018). It is used in tissue engineering and wound healing due to biocompatibility, biodegradability, non-immunogenicity and low cost. Moreover, it contains peptide sequence that recognizes integrin receptors in the cells, which helps in cell adhesion. Gelatin also develops nano-fibrous structure that is important for skin regeneration. Thus, gelatin is able to mimic the extracellular matrix of skin for cellular adhesion, migration and proliferation. Pristine gelatin has low gelling temperature (below 30°C), which hinders its use at the human body temperature. (Zheng *et al.*, 2018). Therefore, it is crosslinked or blended with other polymers to overcome its shortcomings. For instance, gelatin based cross-linked dressing were developed and includes gelatin/alginate and gelatin/hyaluronate and chitosan/hyaluronate to treat full thickened wounds. They loaded silver sulfadiazine in them. Here, gelatin/alginate based sponges with silver sulfadiazine proved to be more effective in healing wounds as compared to other formulations (Choi *et al.*, 2001). Extracellular matrix of skin resembles crosslinked hydrogel network that consists of both polysaccharides and cell-adhesive proteins. Thus to construct a scaffold resembling natural skin, researchers developed methacrylamide-modified gelatin and starch-pentenoate hydrogel films for tissue repair. They also showed gelatin-based hydrogel can be coated with aggrecan (major structural proteoglycan found in the extracellular matrix of cartilage) via physisorption (Van Nieuwenhove *et al.*, 2016). In another study, Li *et al.*, prepared and evaluated composite films as wound dressings by using the combination of gelatin (structural protein of connective tissues) and chitosan (healing promoter and antibacterial). In addition, these films were incorporated with ibuprofen, and were found to be more effective in inhibiting *S. aureus* than *E. coli*. During hemostatic assay these films showed ability to absorb exudate, promoted platelet aggregation, rapid coagulation and clot formation and thus can serve as wound dressings (Li *et al.*, 2017). But these dressings lack any antibacterial properties. So, in more recent study, gelatin/chitosan/silver nanoparticle (Ag NPs), novel composite sponge wound dressing was obtained by crosslinking it with tannic acid. This composite dressing showed good mechanical properties, swelling and more importantly antibacterial effect as compared to the gelatin/chitosan hydrogel dressings. In vivo testing demonstrated, safety, biocompatibility and more importantly reduced the healing time when compared with control, gelatin/chitosan and marketed product called Aquacel® Ag (Ye *et al.*, 2019).

In another study, gelatin-based hydrogels was blended with low content of gellan gum to address the low gelling temperature of gelatin. Electrostatic complexation between gelatin and gellan gum resulted in hydrogel network film at body temperature. To impart antibacterial properties, they loaded tannic acid in hydrogels (Zheng *et al.*, 2018). Türe *et al.*, proposed wound dressing based on gelatin/alginate/hydroxyapatite. They incorporated tetracycline hydrochloride in these composite films, and shown slightly more inhibitory effect against *S. aureus* as compared to *E. coli* the most common opportunistic pathogens of wound area. Moreover, it was observed that swelling ratio and drug release from the films decreased with increasing concentration of alginate and hydroxyapatite but mechanical properties of the films were dependent on the amount of hydroxyapatite and the alginate: gelatin ratio (Türe, 2019). All these studies endorses the use of gelatin as biopolymer for wound dressing.

(c) *Natural gums*

Water soluble natural gums are widely used in pharmaceutical and food industry due to inherent properties such as: high hydration rate, gel forming ability, non-toxicity, wide availability, biodegradability, low antigenicity etc. (Bhardwaj *et al.*, 2000).

i. *Gellan gum*

Gellan gum is anionic, high molecular weight polysaccharide obtained from *Pseudomonas elodea*. Gellan gum is extensively utilized for preparation of composite hydrogel films for various biomedical applications including wound dressings to suppress postoperative adhesions and prevention of scar. It is suggested that gellan gum hydrogels crosslinked by divalent ions possesses excellent mechanical properties, but unfortunately are not stable at physiological pH due to exchange of divalent ions with monovalent ions from biological fluids (Zhang *et al.*, 2020). These limitations are somehow tackled by using its composite. For example, Manda *et al.*, have investigated the potential of gellan gum-hydroxyapatite composites for tissue engineering. In these composites, CaCl_2 and hydroxyapatite reinforced their mechanical properties while gellan gum-hydroxyapatite sponge like hydrogels mimics the organic and inorganic phases of the bone and provide conducive environment for growth of cell at site of injury (Manda-Guiba *et al.*, 2012). Tsai *et al.*, designed the gellan gum-glucosamine patches and loaded with clioquinol via EDC-mediated covalent conjugation to gellan gum/glucosamine. They finally, concluded that these patches are suitable for treatment of early stage cancer and as well as wound dressings after surgery of oral cancer (Tsai *et al.*, 2018). In another study, gellan gum-chitosan hydrogel films were developed by crosslinking it with PEG. They loaded these films with apigenin, a flavonoid rich in various vegetables and plants. Flavonoids are reported to have antioxidant, antibacterial, anti-inflammatory activities and thus can be employed for wound healing application. These films released 96.11% of apigenin in 24 h and during *in vivo* studies apigenin loaded gellan gum-chitosan hydrogel films not only stimulated wound contraction but also significantly enhanced collagen content (Shukla *et al.*, 2016).

ii. *Carrageenan*

Carrageenan belongs to naturally occurring sulphated polysaccharides, and three different types of carrageenan gum are available in market, but mostly kappa carrageenan is employed. κ -carrageenan is widely used as gelling and thickening agent but their films are also investigated as effective wound dressings owing to inherent biocompatibility, it helps in blood coagulation and immune modulation which are helpful attributes for wound healing. Nevertheless, due to poor mechanical properties it is preferred to use it in blended form (Zepon *et al.*, 2019). Literature cites many studies on composite hydrogel films of carrageenan for wound management. For instance, Jaiswal *et al.*, prepared and investigate the carrageenan-chitosan composite films reinforced with grapefruit extract and nanoparticles to be an effective dressing for full-thickened wounds. These composite films showed strong inhibitory effect against *E. coli* and *S. aureus* as well as high healing rate in full-thickened wounds as evident by histopathological images after two weeks of study. It showed thick epidermis, collagen deposition, fibroblast formation and absence of inflammatory cytokines that showed the faster healing rate (Jaiswal *et al.*, 2019). Similarly, carrageenan, agar and chitosan based composite films encapsulated with curcumin have been reported in literature. Uniform distribution of curcumin not only enhanced antibacterial activity but also antioxidant activity of films and thus can be used for food packaging (Roy and Rhim, 2020) as well as wound healing. Apart from above studies literature mentions κ -carrageenan/locust bean gum hydrogel films where authors used cranberry extract (Zepon *et al.*, 2019), to promote wound healing.

iii. *Aloe vera*

Aloe vera is also referred as *Aloe barbadensis* Miller and is widely used in biomedical, pharmaceutical and cosmetic applications. It contains more than seventy-five biologically active constituents and are responsible its antibacterial, antiviral, antifungal, anti-inflammatory, antioxidant and wound healing properties. It contains glucomannan, a water-soluble polysaccharide, which affects fibroblast growth factor from macrophages, which in turn stimulates the activity and proliferation of fibroblast cells. These cells improves collagen production that leads to rearrangement of epithelial tissues (Rahman *et al.*, 2017). Nevertheless, antiseptic, anti-bacterial and anti-inflammatory properties of *Aloe vera* also contributes in healing of wound. Antiseptic ingredients includes salicylic acid, cinnamonic acid, sulfur and lupeol while antioxidant activity results from phenolic and polysaccharide constituents such as mannan, acemannan, glucomannan and flavonoids, flavonols, organic acids (citric acid), etc. (Minjares-Fuentes *et al.*, 2018; Ray *et al.*, 2013). For management of wounds various antibiotics such as minocycline, ofloxacin, gentamycin etc. are used to kill bacterial population responsible for suppressing the wound healing. However, there continues use leads to bacterial resistance. Thus, it would be interesting to use natural biomaterials as wound

dressings with intrinsic antibacterial and wound healing properties such as *Aloe vera* (Pereira *et al.*, 2013a). Moreover, when compared to other polysaccharides, *Aloe vera* has high water swelling efficiency and it can be easily grafted with other polymers due to presence of a large number of functional groups (SaruchiKumar *et al.*, 2018).

So far, several studies have been conducted on use of *Aloe vera* composite hydrogel films as anti-carcinogenic, immune-modulating, anti-ulcer films and as wound dressings for several types of wounds (Pereira *et al.*, 2013a,b; Saleem, 2012). Pereira *et al.*, prepared alginate and *Aloe vera* based composite films by solvent casting-ionotropic gelation method and studied their wound healing properties. They varied the concentration of *Aloe vera* from 5% to 25%, which showed positive influence on transparency and water absorption capacity and thus could be good substitute for wound protection (Pereira *et al.*, 2013b). However, this study lacks the in vivo assessment of developed hydrogel dressing. Similarly, in another study, potato starch/chitosan/*Aloe vera* based hydrogel films were developed with different concentration of *Aloe vera* (10%–50%). *Aloe vera* not only influence thermal stability but also water retention capacity. Presence of *Aloe vera* broadens the scope of films (Bajer *et al.*, 2020) thus can be effectively used for various therapeutic and dressing purposes.

Moreover, alginate/*Aloe vera* hydrogel films obtain by crosslinking with zinc ions (Koga *et al.*, 2020), chitosan/alginate films blended with *Aloe vera* and Ag NPs (Gómez Chabala *et al.*, 2017), alginate/*Aloe vera* hydrogels films obtained by crosslinking with calcium chloride (Pereira *et al.*, 2013c) etc. were found effective in treating wounds. Thus, for wound healing selection of suitable polymers with comparative properties is the major goal of recent research, work of these authors have put a step forward in field of natural polymer based delivery systems for wound management. These systems provide the benefit of using ingredient that not only constitutes dressing matrix but also contributes in prevention of bacterial growth, tissue regeneration and wound repair after it diffuses from composite hydrogel films after its application on wound.

Composite films containing synthetic polymers

Several synthetic polymers have been utilized for synthesis of burn and wound dressings such as polyvinyl alcohol (PVA), polyethylene, polypropylene, polyvinyl chloride (PVC), polyethylene glycol (PEG), polyvinyl pyrrolidone (PVP) etc. due to their good biocompatibility and nontoxic nature (Mogoşanu and Grumezescu, 2014).

i. PVA

It is one of the most frequently utilized synthetic polymer in advanced biomedical field (Kenawy *et al.*, 2014; Kim *et al.*, 2008) for wound management (Zhao *et al.*, 2003), tissue engineering, and drug delivery (Kamoun *et al.*, 2015). However, PVA has limited hydrophilicity, its aqueous solution is transformed to low strength gel (Fathi *et al.*, 2011), which constrain its use as a wound dressing, thus it has been blended with several other synthetic polymers to enhance its mechanical, physical and thermal properties. For e.g., PVA/PVP blended hydrogel films were prepared by crosslinking it with γ -radiation. Wound healing potential of these films was assessed in rat models while comparing it with sterile gauze and Sofra-tulle®. Results showed the better exudate absorption for PVA/PVP blended films than sterile gauze while Sofra-tulle® showed no exudate absorption. Histopathological examination of wounds treated with PVA/PVP blended films showed thick epidermis formation (Razzak and Darwis, 2001). Dextran is Branched poly- α -D-glucosides of microbial origin, is hydrophilic, inert in biological systems, and hardly affects cell integrity. Thus, widely used in pharmaceutical preparations. For instance, Hwang *et al.* developed PVA/dextran hydrogel films which showed low porosity, flat structure, low exudate retention capacity and only showed antibacterial effect after drug loading (Hwang *et al.*, 2010). To overcome such shortcomings first dextran-aldehyde was developed that function as macromolecular cross-linker, and later different concentration of PVA/dextran-aldehyde was crosslinked by freeze-drying. Author claimed that highly porous structure not only absorb large quantity of exudates but also promotes healing. During in vivo studies, PVA/dextran-aldehyde hydrogels have shown promising results when compared with Comfeel® (Zheng *et al.*, 2019). Apart from this study, different authors have prepared PVA/PEG based dressings (Ahmed *et al.*, 2018; Singh *et al.*, 2018; Dutta, 2012) where it was observed that physicochemical and thermal properties of hydrogels were improved after incorporation of PEG.

ii. PVP

PVP is FDA approved non-ionic, hydrophilic, non-toxic, inert, and biocompatible and pH stable polymer. As its structure closely resemble to proteins so it is widely used for biomedical applications and as binder in pharmaceuticals (Liu *et al.*, 2013). PVP blends with other synthetic polymers have been reported in literature as effective wound dressings. PVP/PVA and pomegranate seed nanoparticles based wound dressings were designed by Dogan *et al.*, by freeze thaw method. Findings showed the effectiveness of dressings against *E. coli* and *S. aureus*, thus have potential to be used as wound dressings in infectious wounds (Doğan *et al.*, 2019). Razzak *et al.*, synthesized PVP/PVA blended composite dressings by high energy irradiation method. In their study, authors concluded that these dressings have potential to be used as burn covering dressings as they exhibit good elasticity, effectively absorb exudate and fluids, have good transparency and mechanical properties and act as barrier against microbes (Razzak and Darwis, 2001).

Composite films containing natural and synthetic polymers

Recently the use of combination of natural and synthetic polymers as wound dressings has gained researchers attention as this combination compensates the insufficiencies of thermal stability and mechanical strength of natural polymers. Furthermore, utilization of polymers blend, rather than single polymer; provides the synergistic performance of constituting materials. Following passages will discuss various hydrogel dressing developed by blending natural and synthetic polymers.

Rahmani *et al.*, designed the chitosan, PVA, PVP blended composite films as wound dressing material where chitosan was combined with synthetic polymers to overcome the brittleness, poor physical, mechanical and biological properties of chitosan (Rahmani *et al.*, 2020). Zheng *et al.*, fabricated the dextran/PVA based composite films and these blended composite films were found to be potential dressings for full thickened and cutaneous skin wounds (Zheng *et al.*, 2019). Similarly, several combinations of natural and synthetic polymers have been reported in literature as wound healing materials. For instance, chitosan, PVP and cellulose dressings (Hasan *et al.*, 2017), chitosan, gelatin, PVA based hydrogels for wound healing (Fan *et al.*, 2016), pectin and PVP based membranes (Mishra *et al.*, 2008), xyloglucan and PVA based films for wound healing (Picone *et al.*, 2019), gellan and PVA blends (Sudhamani *et al.*, 2003), chitosan, PEG, PVP dressings (Anjum *et al.*, 2016), gelatin and poly(D,L-lactide-co-glycolide) films (Chung *et al.*, 2016), sodium carboxy methyl cellulose, PEG, PVP wound dressings (Roy *et al.*, 2010), PVA/chitosan hydrogel membranes loaded with ibuprofen- β -cyclodextrins (Morgado *et al.*, 2017). Apart from above studies literature mentions PVA/*Aloe vera* hydrogel films (Hajian *et al.*, 2017), PVP/kappa-carrageenan/PEG hydrogel dressings (De Silva *et al.*, 2011), PVP/carrageenan blend hydrogels with nanosilver (Singh *et al.*, 2015) κ -Carrageenan/PVP/PEG/Ag NPs hydrogel films (Fouda *et al.*, 2015) etc. for wound care management.

Composite hydrogels reinforced with micro and nanocarriers

Micro and nano materials have gained great interest in biomedical application due to their unique and versatile physicochemical properties, controlled shape, specific size characteristics, and modification possibilities. In addition, these particles provide platform for controlled and site specific delivery of drugs, proteins, other bioactive compounds and genes. Metal and metal oxide nanoparticles have antibacterial, anti-fungal, and antiviral activities, while inorganic, semi conductive and magnetic nanoparticles provide the advantage of their use as carrier for hyperthermal, photothermal and photodynamic therapy (Zhao *et al.*, 2015).

Due to aforementioned unique properties, combination of hydrogels and nanoparticles, also known as nanocomposite/hybrid hydrogels have great potential for therapeutic and diagnostic applications. These hybrid hydrogels can be defined as "composite materials incorporated with nano sized materials which are physically or chemically crosslinked in matrix of polymeric network".

Metal/metal oxide nanocomposite wound dressings

Various metal and metal oxide NPs have been investigated due to various therapeutic properties. Among them, Ag NPs have gained more attention due to its broad-spectrum antibacterial activity as well as low toxicity towards human tissues. For example, Ye *et al.*, have designed gelatin/chitosan/Ag nanoparticle composite dressings by crosslinking it with tannic acid. Here, they employed gelatin as matrix agent but it also helped in reduction of AgNO₃ by hydroxyl group of hydroxyproline in gelatin while nonpolar amino acids of gelatin helped to stabilize Ag NPs. Amino group of chitosan, which develops coordinate bonds with Ag⁺, further stabilized these nanoparticles. They observed that gelatin/chitosan/Ag had better mechanical properties when compared with gelatin/chitosan sponges. These composites also showed high inhibitory activity against *E. coli* and *S. aureus* and good water absorption and retention capabilities that kept the wound surface moist for longer duration to promote the wound healing as was evident from histopathological studies that showed development of new skin, absence of inflammatory cytokines and thick epithelia (Ye *et al.*, 2019). Gonzalez *et al.*, prepared wound dressing of PVA/bentonite, PVA/cellulose, PVA/clove extract and PVA/Ag nanocomposite hydrogels by freeze thaw method. They claimed, PVA/Ag NPs and PVA/bentonite showed promising antibacterial activity against *E. coli* and significant vapor transmission rate and high water absorbing capacity, all of these attributes are favorable for wound dressing (Gonzalez *et al.*, 2011). Several other researchers have developed nanocomposites e.g., Ag NPs loaded PVA-acacia gum hydrogels (Juby *et al.*, 2012), hyaluronan, PVA and Ag NPs loaded composites (Zhang *et al.*, 2013), carboxy methyl cellulose and Ag loaded composite hydrogels for biomedical applications (Yadollahi *et al.*, 2015; Hebeish *et al.*, 2013).

Zinc oxide (ZnO) is another important element whose NPs have been intensively investigated for biomedical applications. They have shown promising antibacterial affect against various pathogens after penetration of bacterial cell wall via diffusion. It causes death by disintegrating the bacterial cell membrane and via interaction with various biomolecules in cytoplasm (Siddiqi *et al.*, 2018). Owing to antibacterial properties, they are also finding their way into hydrogel based wound dressings. For instance, chitosan/PVA films were incorporated with different concentration of Tween 80 and ZnO NPs. Presence of these two components affected thermal, mechanical and antibacterial properties of composite hydrogel films. So, authors suggest that these films may be used as effective dressing for wound and burn (Vicentini *et al.*, 2010). Sudheesh *et al.* prepared chitosan and ZnO nanocomposite microporous films with high swelling and vapor transmission rate. They showed excellent antibacterial activity against gram-positive bacteria. During cell attachment and infiltration studies, cells attached with nanocomposite bandages. Histopathological study showed faster re-epithelization and collagen deposition owing to ZnO encapsulation. Authors suggested that these dressings can be used for chronic, diabetic and burn wounds (Sudheesh Kumar *et al.*, 2012). Păunica *et al.*, proposed dextran-collagen-ZnO NPs based nanocomposite films as wound dressings. Under electron microscope, these composite films presented a three-dimensional porous structure with interconnected pores that depends on concentration of dextran and ZnO NPs. Dressings obtained with collagen and dextran presented a more compact structure with smaller pores when compared with one developed with neat collagen. Based upon the rheological, water absorption properties, biological investigations, and degradation studies composite hydrogel based on collagen and dextran with ZnO (50% of collagen weight) were deemed optimum for patients with different wounds. However, this study lacks the in vivo wound healing testing that gives an insight into healing potential and mechanism (Păunica-Panea *et al.*, 2016). In another study, alginate and ZnO NPs (0.05% to 1% w/w) composite bandages were designed for management of infected wounds. These nanocomposites were porous and their porosity decreased in the presence of nanoparticles that could be due to the interaction of alginate with ZnO NPs. Their swelling ratio also decreased with increasing

concentrations of ZnO. These dressings showed excellent antimicrobial activity against strains of *methicillin resistant S. aureus* and other tested bacterial strains. Furthermore, *in vivo* studies showed rapid re-epithelization and keratinocytes migration (Mohandas *et al.*, 2015) to wound site owing to release of zinc ions, which promotes wound healing. Apart from these studies, several other ZnO nanocomposite hydrogel bandages were investigated for wound healing (Luo *et al.*, 2020; Kumar *et al.*, 2013). Thus, addition of metallic nanoparticles to hydrogel wound dressing helps to reduce the bioburden at wound site and providing conducive environment for proliferation of cells.

Carbon based nanocomposite wound dressings

Carbon based nanoparticles have gained popularity in past few decades due to their excellent physicochemical properties. Among them graphene based nanomaterials have been explored as biomaterials for various biomedical applications (Zhao *et al.*, 2015). Fan *et al.*, have developed Ag/graphene composites hydrogels with acrylic acid and N, N'-methylene bisacrylamide as wound dressings. Presence of graphene in hydrogel enhances the tensile strength and elongation break of hydrogel, and thus meets the mechanical strength necessary for wound dressing. These dressing were porous and porosity increased with increasing concentration of Ag NPs, whereas swelling ratio was also highest in formulation with higher quantity of Ag NPs. As porous structures helps to provide sufficient oxygenation, absorbs exudates and maintain moist environment at wound site, thus considered as optimum formulation. These highly porous dressing with high silver content demonstrated good antibacterial activity and promoted healing in artificial wounds (Fan *et al.*, 2014) owing to synergy of Ag NPs and porous graphene structure.

In another study conducted by Usman *et al.*, PVA, starch, graphene oxide and Ag NPs based nanocomposite films were prepared for biomedical applications. Here, also incorporation of graphene oxide enhanced the tensile strength of the nanocomposites films. Furthermore, these films showed significant antibacterial activities against both gram positive and gram negative bacteria. Their antimicrobial activity was in order of PVA-graphene oxide < PVA-Ag < PVA-graphene oxide-Ag < PVA-graphene oxide-Ag-starch films (Usman *et al.*, 2016). Graphene oxide, has reported antimicrobial properties and are strongly affected by its physicochemical properties (sheet size, surface area, purity, structural defects, surface chemical properties, functional groups and degree of oxidation). Furthermore, its antibacterial activity is concentration, time and medium dependent (Cobos *et al.*, 2020). Although synergy of graphene oxide and Ag NPs showed good results but underlying mechanism was not clearly demonstrated. In another study, graphene oxide – silver nanocomposites were developed that showed more toxic effects on *E. coli* than *S. aureus*. The proposed mechanism suggests bactericidal action against the *E. coli* by disrupting bacterial cell wall integrity, whereas it exhibits bacteriostatic effect on the *S. aureus* by inhibiting cell division (Tang *et al.*, 2013).

Other nanoparticles based composite wound dressings

Several other studies have been conducted where numerous other nanoparticles were incorporated into polymeric system for healing of wounds, for example, silver sulfadiazine particles were incorporated into bacterial cellulose based dressings for healing of burn wounds (Wen *et al.*, 2015), poly (ϵ -caprolactone) and gelatin based hydrogel films containing cerium oxide nanoparticles as wound dressings (Zheng *et al.*, 2019). Hsu *et al.*, designed the chitosan-PVA nanocomposite films incorporated with gold nanoparticles and investigated their healing potential. These films showed excellent healing rate with high fibroblast proliferation (Mala *et al.*, 2019). Jaiswal *et al.*, prepared carrageenan and chitosan based hydrogel films encapsulating sulfur nanoparticles and grape fruit seed extract for wound healing purpose. These films showed strong inhibitory activities against *E. coli* and *S. aureus* as well as showed high healing rate in full-thickened wounds as confirmed by significant growth of dermis with high contents of collagen, fibroblasts, sebaceous glands and hair follicles by histopathological studies (Jaiswal *et al.*, 2019). Work of these researchers on use of various organic and inorganic nanoparticles in wound dressings, provide evidence that these nanoparticles gives functional properties to hydrogel based wound dressings and are effective for various dermatological treatments. Ion release from nanoparticles is main healing mechanism where free radical stress in bacteria leads to bacterial killing.

Microparticles based composite wound dressings

Only limited studies report microparticles embedded in hydrogel matrix for wound healing applications. For instance, gellan gum microspheres were prepared with tetracycline hydrochloride and silver sulfadiazine. Later these microparticles were embedded into double crosslinked composite of modified carboxymethyl chitosan and oxidized gellan gum. They double crosslinked the matrix using Schiff base-mediated crosslinking together with ionic crosslinking to overcome instability issues of gellan gum hydrogels at physiological pH (Zhang *et al.*, 2020).

Bilayer hydrogel films

As it has been shown by research that composite films have better physicochemical and thermal stability as compared to single entity based films, similarly, bilayer composite films are gaining preference over single layer films as they make better use of or combine the advantages of unique properties of all substrates (Thu *et al.*, 2012). Term of “bilayer films” was coined by Rivero *et al.*, who developed two hydrocolloids layer, one casted over another, having different constituents in inner and outer layer (Rivero *et al.*, 2009). Bilayer films can be defined as “delivery systems that contain more than one active pharmaceutical ingredient in different layers at same time”. They may provide potential to use two different drugs individually in different layers (Zaman *et al.*, 2018) so as to avoid incompatibility and achieve different release pattern for individual drugs. Now a days, extensive research is carried out over bilayer composite films in biomedical, bioengineering and food technology due to their high mechanical strength,

better optical and gas barrier properties, moisture retaining properties, and ease of preparation (Zhuang *et al.*, 2018). Literature reports use of bilayer films as topical wound dressings, edible films, mucoadhesive films and for food packaging.

Thu *et al.*, designed and synthesized the sodium alginate and gelatin based single as well as bilayer films as wound dressings. Only sodium alginate was used in single layer while in bilayer film either sodium alginate alone or in combination with gelatin was employed for both layers. Here, upper layer was loaded with ibuprofen while lower layer was drug free and acted as rate controlling layer. These bilayer films hydrate slowly and releases the drug in controlled manner as compared to single layer films thus are ideally suited for low suppurating wounds or where slow release of active ingredient over wound is required. It was observed that artificial wound treated with bilayer films healed faster than single layer film (Thu *et al.*, 2012). It's probably because blend of sodium alginate and gelatin reported to show hemostatic effects and enhanced epidermal regeneration (Coviello *et al.*, 2007). In another study, gelatin and chitosan based bilayer films were designed for wound healing purpose. Upper layer of dressing was composed of lactulose crosslinked gelatin to produce a resistant and non-degradable layer that provided mechanical strength while lower layer was composed of citric acid crosslinked gelatin (having high porosity, swelling and degradability) with chitosan that also promotes wound healing. These bilayer films showed above 90% wound contraction in *ex-vivo* wound healing assay (Garcia-Orue *et al.*, 2019). In a more recent study, diclofenac sodium loaded alginate and carboxymethyl cellulose based monolayer and bilayer films were developed by Travisol *et al.*, as wound dressings. They incorporated diclofenac sodium in upper layer of bilayer film to favor slow drug release, as lower drug free layer will act as barrier to mass transfer. Encapsulated drug released over a period of 420 min and 600 min for the mono and bilayer films, respectively. Authors concluded that monolayer film could be utilized for fast pain relief and bilayer film could be effective for wound healing due to controlled drug release (Trevisol *et al.*, 2020). Similarly, many other studies are reported in scientific literature. Chitosan and konjac glucomannan based bilayer films were synthesized as wound dressings (Neto *et al.*, 2019), bilayer membrane consisting of an outer poly(lactic-co-glycolic acid) layer and a lower alginate hydrogel layer, which mimicked the skin epidermis and dermis respectively (Wang *et al.*, 2019), bilayer dressing containing chitosan-oxidized *Bletilla striata* polysaccharide (lower layer) and chitosan-Ag both cross-linked with genipin (upper layer). Here, upper layer provides antibacterial cover while lower layer enhanced the cellular proliferation (Ding *et al.*, 2017), bilayer PLGA/PVA dressing containing stem cell and Ag NPs for wound healing. PLGA layer was developed by electrospinning and contains Ag NPs for antibacterial cover, while stem cells were seeded in PVA hydrogel layer to promote cellular proliferation (Gao *et al.*, 2020).

Hydrogel Based Products in Market

Hydrogels as polymeric dressing are becoming the main commercial target. Several commercial hydrogels have appeared in market as dressing materials. Some of those, with their brand names are discussed below;

(1) *Geliperm*®

Geliperm® sheets are transparent hydrogels with 96% water. These sheets are made up of gellable polysaccharides i.e., agar and polyacrylamide (4%) forming an interwoven molecular network. It is recommended for treatment of acute or chronic wounds involving skin or tissue loss, from burns, dermabrasions, and superficial sores. These highly porous dressings are permeable to gases, water vapors and small protein molecules but impermeable to bacteria, thus provides optimum moist environment at wound site, which is necessary for effective wound healing. Moreover, these dressings also reduce discomfort and local pain.

(2) *Curasol*®

Curasol® gel wound dressings are viscous and clear hydrogels mainly composed of glyceryl polyacrylate and humectants. They are recommended for treatment of low exudating wounds. These highly hydrated dressings provide appropriate moist environment at wound site with mildly absorbent properties. These are fragrance free, non-greasy, and non-inflammatory in nature.

(3) *Tegagel*®

Tegagel® is available in form of sterile fibrous sheet, made up of calcium alginate. These sheets upon contact with solutions of sodium ions, serum or wound exudate, converts to soluble sodium alginate and form a gel on sheet surface. These sheets are recommended for exudating wounds, pressure sores and for diabetic wounds. These dressings provide such environment that facilitates the rapid wound healing and protection against microbial invasion.

(4) *Vigilon*®

Vigilon® hydrogel sheets contain 96% water and are made up of crosslinked polyethylene oxides. These sheets are further strengthened by low-density polyethylene and are recommended for variety of wounds except heavily exudating wounds.

Conclusion

Wound healing is a dynamic process that requires a specific moist environment to encourage earlier wound closure. Variety of dressings from traditional to modern ones are available but selection of specific dressing is crucial for effective wound healing. Traditional dressings may reinjure the wound, as well as are permeable to bacteria, thus, researcher are working on modern dressings such as hydrogel films which effectively inhibits growth of microorganisms and promote healing cascade by stimulating

fibroblast formation. However, composite films were found more effective and suitable for wound care management and includes composite films developed using blend of natural or synthetic polymers, bilayer films, films blended with micro and nanoparticles. It is evident from studies that development of composite films, overcomes shortcomings of single polymeric system by improving the mechanical, physicochemical, thermal stability, and antibacterial of films. Furthermore, incorporation of micro or nanoparticles, or different bioactive materials in different layers of films has proven as an innovative mean to improve robustness and impart multiple functionalities to hydrogel dressings.

However, besides the major progress in composite films, there are still some challenges that must be overcome before their clinical use. As nanoparticles provide large surface area so hydrophobic nanoparticles may have embedded or form aggregates in polymeric matrix so their homogeneity in polymeric matrix is still a matter of concern. Secondly, despite limited in vivo studies their long term toxicological and tissue compatibilities studies are needed before marketing.

Introduction of Composites

In terms of defining, composite is a combination of two or more components having different chemical as well as physical properties to acquire superior characteristics which cannot be acquired by any of the component on its own (Hashin, 1983). The word composite may sound new but it is as old as human history. The key point of the above-mentioned definition is creating something new by combining different materials. One of the best and oldest examples of a composite is adding straws to the mud to attain greater strength. Even nature has its own composites and some of the most prominent examples are leaves, wood and bone (Clyne and Hull, 2019).

At this point composites may seem like a blend or an amalgam of different materials but there is a striking difference between these two systems. In a blend or amalgam the individual components do not retain their identity however if we look at mud wall straws and mud have not lost their individual identity (Jones, 1998).

The usability of composite is not only limited to mud wall or wood instead the appliance of composite material has ached mankind into an era of airships, orthopedic devices, satellite systems, bulletproof vests, organ reconstruction and much more (Ngo, 2020).

Composition of a Composite

In general, a composite material comprises of three elements, which include a matrix, one or more reinforcement materials and an interface. Matrix and reinforcement are two major constituents of a composite material whereas the interface is the zone between them. The basic parts of a composite material system is presented in Fig. 1.

- (1) The material in bulk in a composite is called matrix. It is also known as continuous phase. The main role of a matrix is to act as a link and hold the reinforcement material in it. In addition, it must possess the capability to relocate the stress to the reinforcement material in it. Most frequently used matrix are divided into three group which include metals, ceramics and polymers (Jose and Joseph, 2012).
- (2) The material, which is dispersed in the matrix, is called reinforcement. It is also known as dispersed phase and its main function is to impart different properties to the system. Variety of reinforcement material has been studied throughout literature and each has the ability to impart different property to the composite. Some commonly used reinforcement material are fiber, particulate and laminates (Pastuszak and Muc, 2013).
- (3) Interface is not only responsible for relocating the stress from matrix phase to reinforcement phase but it can also influence the strength and overall properties of the composite system. At the interface, different types of bonding can be seen such as physical, chemical and mechanical. Stronger bonding imparts high strength to the composite but lower the toughness of the material and vice versa. Among all bonds chemical bond is strongest of all but it is avoided in the biomedical applications due to biocompatibility issues (Jesson and Watts, 2012).

Classification of Composites

Composites can be grouped on more than one basis however they are in general classified on the base of their constituents i.e. matrix and reinforcement. Different types of composites are mentioned in literature depending upon their constituents. On

Fig. 1 Basic parts of a composite material system. Reproduced from Cech, V., Palesch, E., Lukes, J., 2013. The glass fiber–polymer matrix interface/interphase characterized by nanoscale imaging techniques, *Composites Science and Technology* 83, 22–26.

the base of the matrix, they are grouped into polymer matrix composite (PMC's), metal matrix composites (MMC's) and ceramic matrix composites (CMC's) and in case of reinforcement material they are divided into laminate composites, particulate composites and fibrous composites. However, in this article our focus will be polymeric matrix composites. (Balasubramanian, 2016).

Polymer Matrix Composites

A polymer matrix composite is generally defined as the material consisting of fibers either continuous or discontinuous, which are held together by the polymeric matrix. The only condition for a composite material to be considered polymeric in nature is to contain an organic polymer as its core or matrix. The addition of the term fiber in the definition comes from the extensive use of fiber to reinforce polymer. Such type of composites are typically known as fiber reinforced polymer composites. (Park and Seo, 2011) Like discussed above a reinforcing material can be particulate as well as laminate too. The only motive behind using fibers to reinforce polymers is their ability to efficiently carry load and improve the mechanical strength and stiffness of the composite system, which is lacked by the polymer matrix. Besides, in comparison to the other elements such as particles and laminates they own greater aspect ratio making them superior in strength. Some of key strengths of using fiber as reinforcing element are High modulus, High mechanical strength, Good corrosion and fatigue resistance, Lower cost, Easy fabrication methods, Good wetting properties and Multi-functional performance (Rajak *et al.*, 2019).

Polymers Used in PMCs

Fabrication of polymer composites involves varieties of polymer such as thermosetting polymers, thermostat polymers, elastomer and resorbable polymers. Furthermore, blends of these polymers can also be utilized however; selection of the polymer will be dependent upon the characteristics required of the composite system.

(1) Thermoplastic polymers:

These are high molecular weight polymers and their structure includes both linear as well as branched chain molecules, which are bonded by strong intra, and weak inter molecular bonds. In case of heating or applying pressure, these polymers cannot hold their shape and show softening or melting. As composites, they exhibit excellent stability and can be easily shaped into the desired contour exclusive of degradation. Examples include polyethylene, polypropylene, nylons, polystyrene, polyacetals, polysulfones (Wolf, 2000).

(2) Thermosetting polymers:

Reshaping phenomenon observed with the above-discussed type is unseen in these types of polymers. Their structure involves cross-linking and covalent bonds. As matrix, it shows curing phenomenon whereby polymer chain start to cross-link and gather the entire matrix in a 3D structure, which offers higher stability and temperature resistance. Epoxy, polyacrylates, polymethacrylates, polyesters, polyimides and ureas are some of the most prominent examples of this class (Rudyak *et al.*, 2019).

(3) Elastomers:

Polymers having high elasticity like rubber are known as elastomers. Their structure exhibit light cross-linking and weak bonding forces due to which they can be deformed easily. Besides, they also have a low modulus and glass transition temperature below room temperature. Natural rubber, silicone rubber, polysulfide rubber and thermoplastic elastomers are some of the commonly used examples. (Cardarelli, 2008).

(4) Resorbable polymers:

Resorbable polymers entail biodegradable chains, which can be degraded or dissolved in the body over time. Because of monomers along with species having small molecular weight are released which are engrossed by metabolic pathway. These types of composites materials are used majorly used in designing implants to bypass the need of surgical intervention to remove them. Some important resorbable polymers include poly lactide (PLA), poly glycolic acid (PGA), poly caprolactone (PCA) etc (Krishnamoorthy *et al.*, 2019).

Reinforcing Elements Used in PMCs

Among reinforcing materials, fiber is one of the most highlighted material for reinforcing polymer and is extensively employed in designing (Arpitha *et al.*, 2014). A typical fiber is produced as a continuous filament having diameter varying from 3 to 200 μm and can be assembled to manufacture yarn, town or mats. This fiber is known as long or continuous fiber and the composites reinforced by it are known as continuous fiber composites. However, the length of this fiber can also be decreased up to 0.02–100 mm. Such type of fibers are known as short or discontinuous fibers and they are involved in designing discontinuous fiber composites (Staab, 2015). Fibers can be oriented in different directions but they are mostly oriented in the direction of the stress to enhance the stress bearing capacity of the fibers. Even though both continuous and discontinuous fibers can be oriented but it is a little difficult to orient discontinuous fibers in comparison to long filaments (Campbell, 2010).

Types of fibers

(1) Natural fibers:

Fibers produced by plants, animals and geological processing are known as natural fibers. They are found abundantly in nature and are easily available but they display problems regarding processing which makes them costly and undesirable. In addition, their properties vary extremely. Some common examples of natural fibers include wood, wool, cotton, silk, jute and collagen (Taj *et al.*, 2007). Due to an increased trend of using natural materials for the sake of environment, researchers are more inclined towards using them.

(2) Synthetic fibers:

Synthetic fibers are manmade fibers that are synthesized chemically. In comparison to the natural fibers, they are more advantageous in terms of cost, properties as well as stability and are widely used in large number of application fields (Mahlitig and Kyosev, 2018). Use of these fibers in the fabrication of PMCs is extensive and can be found throughout the literature. However, some of the most pertinent examples are discussed below:

● Carbon fiber:

Carbon fibers (CF) consist of more than 90% of carbon atoms which are attached together to form a long chain with a diameter of 5–10 μm . These fibers are well known for their high strength, stiffness and lower weight making them an ideal candidate for use in prosthetic designing. In addition, carbon is inert in nature and it does not impede neotissue growth owing to this property. Instead, some studies also supported its positive role in enhancing the neotissue growth. Fabrication of carbon fibers involves using a precursor as raw material since pure carbon cannot be used for this purpose. The most widely used precursor is polyacetonitrile (PAN) (Pico and Steinmann, 2016; Kumar *et al.*, 2018).

● Glass fiber:

These fibers are fabricated by melting silica followed by extrusion and attenuation to form filaments, which are further thinned by drawing. In terms of strength, they are inferior to carbon fiber. However, they exhibit little brittleness and are less costly as compared to CF. Also due to their transparency, resistant nature and biocompatibility they are widely used in dental composite fabrication. Apart from that they also used as biomaterials for orthopedic implants and their components (Mahlitig and Kyosev, 2018; Syed *et al.*, 2019).

● Polymeric fiber:

Due to their versatile nature and greater resemblance with extra cellular matrix, fibers are majorly employed in tissue engineering. Basic method to manufacture polymer fibers is spinning polymer solution followed by stretching. Spinning turns the solution to a fibrous form whereas stretching orients the polymer chains enhancing the modulus as well as strength of the fiber (Bhat and Kandagor, 2014). Most frequently used polymer fibers include aramid fibers (Kevlar T^M), Polyethylene fibers and Poly ethylene glycol terephthalate fibers (Dacron T^M). Resorbable Fiber such as PLA, PLGA, PGA consist of resorbable polymers and are used where dissolution of the composite is required which is necessitated to decrease the mechanical properties over time or to address the issue of removing the implant with surgery (Ratner *et al.*, 2004).

Properties of PMCs

Designing a PMCs involve considering a large number of variables which can shape the overall properties of the system. Each constituent has its own properties and it will affect the composite system depending upon these set of properties. Apart from these, some other variables are important, which include shape and orientation of dispersed phase as well as interfacial adhesion. (Atay, 2016) In order to obtain an optimized composite material each of these factors should be controlled vigilantly.

(1) Shape and orientation of dispersed phase:

All the reinforcement materials have different shapes and orientations and each can influence composite system in its own unique way. Such as fibers which can be long or short and are oriented in a direction to which stress is applied to impart more strength to the system. Similarly, laminates are in the form of sheet having multiple layers, which are oriented to provide increased strength from two directions. Subsequently particles can be sphere, cube, regular or irregular in shape with no favored direction (Clyne and Hull, 2019).

(2) Interfacial Adhesion:

The performance of a composite system is heavily dependent on the ability of matrix and reinforcement materials to adhere to each other. The adhesion can be physical, mechanical or even chemical. Greater the adhesion superior will be the properties in terms of strength and stability (Sottos and McCullough, 1994).

Manufacturing Methods of Polymer Matrix Composites

A large number of methods are involved in manufacturing polymer matrix composites such as pultrusion, hand layup, Spray layup, filament winding, resin transfer molding and injection molding. The key strength of all these methods is easy and less costly fabrication. However, they can be divided in two types based on molds. The mold can be open as well as closed. Subsequently the selection depends on the type of end product required as well as desired application. When the polymeric matrix is in contact with the atmosphere it is termed as open molding method also known as contact molding whereas the latter involve no such contact as

the matrix is enclosed in the mold (Kesarwani *et al.*, 2015). In terms of price, open molded methods are less costly in comparison to closed molded one. In addition, the final products obtained by both are poles apart. The former ones are mostly used when there is a need to produce bulky sized parts but they are also important in producing small parts when cost is an issue. Closed molding is used when the surface of material is supposed to be smooth from both sides as well as to produce accurate parts in bulk (Zulkepli *et al.*, 2019).

Open molded methods

(1) Hand lay up:

It is a very simple and popular technique, which involves layering matrix and reinforcing materials in an open mold by hand. The reinforcing fiber can be continuous, chopped or even woven. One of the biggest advantages offered by this method is higher quality but it is limited by very low production rate. In order to fabricate a high quality polymer composite, an antiadhesive agent followed by another coating also called gel coating to ensure easy release and enhance the quality of the surface respectively usually covers the mold. The reinforcing material is then arranged and covered by resin, which should be evenly distributed. Each layer is stuck to the previous one and if needed rolled to avoid any air pockets. These impregnated layers are then cured and removed from the mold (Cripps *et al.*, 2000; Raji *et al.*, 2019).

(2) Spray up:

This technique is similar to the former technique except it is less rigorous and time consuming than the previous one. In addition, the properties of the composite material such as thickness and the quality lies on the expertise of the machinist. The basic mechanism involves spraying the matrix and reinforcing fibers with the help of a spray gun or jet. Both liquid polymer and the reinforcing material are sprayed concurrently into mold at a preset ratio followed by rolling to remove any air pocket and curing. Furthermore, the fibers are chopped before spraying, as it is not suitable for continuous fibers. This method offer uniform coating but the mechanical properties are lower as compared to hand layup method due to short length of fibers and their random orientation (Cripps *et al.*, 2000; Raji *et al.*, 2019).

(3) Filament winding:

This method involves winding of long filament bundles around the mandrel that is continuously in a rotating motion followed by curing in the oven to solidify the material. Winding can be helical, in loop or in polar style. Although this method is majorly used for thermoset matrixes but in case of thermoplastic material, the mandrel is heated before winding. The first step involves impregnation of the reinforcing fibers bundles with the resin, which is usually done in resin bath. After the impregnation comes winding which can be performed at different angles and in different patterns. Because of winding, a hollow tubular structure is obtained which is first cured and then subsequently removed from the mandrel (Mack and Schledjewski, 2012; Quanjin *et al.*, 2018).

Closed molded methods

(1) Pultrusion:

As indicated by the name this technique is a combination of two things i.e., pulling and extrusion. Fiber from the creel is pulled in to the guided plate to make a bundle of the fibers, which is further guided in to the resin bath where impregnation of the reinforcing material takes place. To shape the composite, the impregnated fibers pass through a device known as performer before entering the die. Performer remove excess matrix from the fibers. In the die, curing take place and the final product is extruded out from the die in the form of rods and beams. This method is best for making composite material rods and beams of high strength because of high fiber fraction. Also the reinforcement provided by this method is continuous (Wilson, 1998; Joshi, 2012).

(2) Resin transfer molding:

This method includes using a closed mold, which provides a better quality finishing product and it usually engage thermosetting resins and continuous fibers. The process entails using three things, which include a closed mold, a transfer pot and a plunger. The first step involves the placement of precut reinforcement material inside the closed mold followed by heating of matrix in the transfer pot. If any additives required they are usually added at this stage along with matrix. After that plunger, forcing it in to the mold presses the resin and additives. The mold is equipped with heater to allow the thermosetting polymer to cure and form crosslinked structure. Ejection takes place after the curing of the matrix because a thermoset matrix retains its shape however in terms thermoplastic resins cooling is required. In comparison to open molding techniques this process is faster and it can produce complex shapes but it necessitates skillfully intended molds (Laurenzi and Marchetti, 2012; Sozer *et al.*, 2012).

(3) Injection molding:

This method is majorly used for processing of discontinuous fibers. The method involves feeding blend of polymer and short fibers in pellets form to the hopper, which conveys the pellet to heated barrel having reciprocating screws, which along with rotary motion can also move forward and backward. The forward movement is intended to shift the fed from hopper to mold followed by the backward shift. Inside heated barrel, mixing takes place followed by forcing it through a small cavity to the mold. The configuration given by mold hardens and solidify upon cooling. This method is advantageous in many ways, which include fastest rate, complex shapes, high rate of production, higher volume and tolerability, but it is limited in terms of fiber length, as well as their orientation across the matrix material. As far as matrix is concerned thermoplastic materials are

Table 1 Examples of different polymer composites employed in reconstructing different organs

Application		Polymer composites (reinforcing element/matrix)	References

preferred but thermosetting polymers can also be used but they require curing which can take place during heating inside the barrel (Kamal and Isayev, 2012; Liu, 2012).

Applications of Polymer Composites

Applications of polymer composites can be found in various fields of life but in this article, we will only focus on organ reconstruction. Reconstructing an organ is better approach to manage damaged organs as compared to transplant but reconstructing a whole organ is not an easy task (Stoltz *et al.*, 2017). Different researches are being conducted to achieve this goal and because of these efforts, different bones, teeth, joints and even tissues can be reconstructed successfully. An overview of these published reports are presented in Table 1, which briefly summarizes some examples of polymer composite materials employed in reconstructing different organs.

Bone reconstruction

Human body consist of approximately 206 bones which combinedly frames the skeletal system and give support to the body however these bones can modify or even break under high stress conditions (Matassi *et al.*, 2011). Fixing a bone can be done in two ways. First, one is external fixing with the help of casts or splints and second one is internal fixation, which is a surgical procedure and is done in serious conditions where bone needs to be supported by using orthopedic implants until the healing has occurred. After the complete healing of the bone these implants are removed from the body. These implants are commonly known as bone plates and intramedullary nails (Saad *et al.*, 2018). In the beginning, these supporting systems were made of metal and titanium however, the modulus of these materials was higher in comparison to bone, which caused the bone to lose its density due to absence of typical stress and fracture again once these implants are removed. This phenomenon is also known as shear shielding. To avoid this phenomena a material having modulus closer to bone as well as sufficient mechanical strength was needed making polymers a suitable option (Ritchie, 1988; Saad *et al.*, 2018).

(1) Bone plates:

Using polymeric composites different types of bone plates can be fabricated. In the beginning, non resorbable composite plates were made using epoxy polymer (Bradley *et al.*, 1980; McKenna *et al.*, 1980) as bulk phase (CF/EPOXY, GF/EPOXY) (Fig. 2(a)), but due to their toxic effect on the body, they were replaced with thermoplastic matrixes like carbon fiber reinforced PMMA, CF/polypropylene, CF/PE, CF/polysulfone, CF/nylon and CF reinforced PEEK (Fig. 2(b)) due to their toxicity free application and ability to bent by heat (Krebs *et al.*, 1997; Fujiyama *et al.*, 2001; Jockisch *et al.*, 1992). Although these composite plates were a success but healing process can be made more efficient by making the plate to lose its rigidity with time which was accomplished by using polymers which are resorbable in nature. However, plates manufactured by using these polymers lack the mechanical strength required to hold the bone, which was enhanced by reinforcing with fiber. If the reinforcing material used is resorbable in nature, then these plates will be known as resorbable composite plates and if it is non resorbable such as carbon fibers and polyamide fibers, then it will be known as partial resorbable composite plates (Ahmed *et al.*, 2011; Mehboob and Chang, 2014).

(2) Intramedullary nails:

These are rod like structures, which are placed in the intramedullary cavity of the femoral-neck bone and inter trochanteric bone. In comparison to bone plates they are used to fix long bone fractures owing to their better mechanical support which is attributed to their central placement on the bone (Hench, 2005). One of the most successfully used material for the fabrication of the

intramedullary nails is CF /PEEK composite (consisting of polyether ether ketone polymer which is reinforced with glass fiber) is shown in **Fig. 3** which exhibited good mechanical properties along with biocompatibility (Vles *et al.*, 2019).

Joint replacement

Joints provide mobility to the body and with regard to design; mostly joints are located between two bones and are shielded and lubricated by a layer of cartilage and synovial fluid respectively. Like bones, joints can also be injured permanently or deteriorated with time due to any disease such as arthritis, which is one of the leading causes of affecting joints. Joint implant is a permanent placement of an artificial joint in the body in order to replace damaged joints. Most common joint implants are knee and hip replacement.

(1) Hip replacement:

The design of the hip replacement implant basically contains a femoral stem and an acetabular cup in which the head of the stem is fixed (Arun *et al.*, 2014) and the material used for its manufacturing include cobalt and chromium alloy, alumina and zirconia, titanium alloy and stainless steel (Pramanik *et al.*, 2005). A hip replacement implant is shown in **Fig. 4**. To avoid metal particles, John Charnley utilized a polymer named Polytetrafluoroethane (PTFE) in 1956 for making of cups owing to its stability and inertness, which under stress showed high wear damage and even tissue reaction. It was later replaced by ultra-high molecular weight polyethylene (UHMWPE) with metallic backing, which also proved to be failure in the long run. It showed creep phenomena as well as erosion which was attributed to metal backing (Merola and Affatato, 2019). To avoid this failure, polymer composites of UHMWPE were used by reinforcing with carbon fibers (CF). They not only bypassed creep phenomena but also provided superior bone bonding and longer life (implant). However these effects were contradictory as some studies negated these benefits (Rushton and Rae, 1984). Due to the concerns with CF polymeric (UHMWPE) fibers were used to reinforce UHMWPE polymer (Deng and Shalaby, 1997). Similarly polyether ether ketone has also been successfully utilized in manufacturing of acetabular cup (Merola and Affatato, 2019). As far as stems are concerned, one of the biggest issue associated with metallic stems is the difference in the stiffness of the metal and bone, which cause the bone to resorb and ultimately cause the implant to loosen up. This issue could be reduced by using alloys such as co-cr alloy and titanium alloy but In order to resolve it such material is required which is comparable in stiffness to bone as well as strong too. To achieve this goal different types of composite material were used by researchers owing to their unique properties and some major examples include CF/EPOXY and CF/PEEK. Although these polymeric composites are more advanced as compared to conventionally used material and offer more advantages in comparison but they are still not in practice (Karihaloo *et al.*, 2003).

(2) Knee replacement:

Knee is a very complicated joint and replacing it involves replacing femur and tibia bone. Building material for femur bone component involve co-cr and Ti alloys whereas for tibial bone ultra-high molecular weight polyethylene and metals are used (Carr and Goswami, 2009). An implant of knee replacement is presented in **Fig. 5**. UHMW polyethylene was reported to

Fig. 4 Hip replacement implant. Reproduced from Hickok, N.J., 2017. Joint implants: An elution solution, *Nature Biomedical Engineering* 1 (6), 0087.

Fig. 5 Knee replacement implant. Reproduced with permission from OrthoInfo. © American Academy of Orthopaedic Surgeons. <http://orthoinfo.aaos.org>.

undergo creep phenomena because of which implant started to sinking. To avoid this phenomenon, it was reinforced with carbon fiber. The reinforcement demonstrated good results in regard to strength and sinking however its effect on wear damage were contradictory (Saad *et al.*, 2018).

(3) Bone cement:

Artificial joints are fixed to the bone by using a material known as bone cement. Acrylic bone cement is one of the most extensively used bone cement. It is self- polymerizing in nature and basically consist of two components i.e. PMMA in powder form and MMA monomer in liquid state (Kaivosoja *et al.*, 2013).The drawback of this cement is that it can cause bone necrosis locally. Due to its polymerizability temperature of the local tissue gets raised and monomers are released in the

Fig. 6 A dental post restored tooth. Reproduced from Panitiwat, P., Salimee, P., 2017. Effect of different composite core materials on fracture resistance of endodontically treated teeth restored with FRC posts. *Journal of Applied Oral Science* 25 (2), 203–210.

blood. Due to increased temperature necrosis may occur (Kaivosoja *et al.*, 2013) but it can be avoided by reinforcing the bone cement with variety of fibers such as inorganic fibers (Kevlar carbon stainless steel, Ti alloys) and polymeric fibers (UHMWPE, PMMA) which along with subsiding necrosis also enhanced the strength. Despite being more effective these fiber reinforced bone cement are not found in practice due to following reasons (Shalaby and Salz, 2006).

1. Viscosity of bone cement increase by reinforcing.
2. Achieving uniform distribution of fibers throughout bone cement is difficult.

Dental reconstruction

The scope of polymer composites in dental field is higher and can range from restoring a tooth to replacing it. Variety of PMCs are used in dental treatments such as dental restoration, veneering and dental post. Each treatment details have been mentioned below.

(1) Dental restorative materials:

Dental composite resin consisting of polymer matrix and a filler is used for the purpose of filling dental cavities as well as veneering. Polymers that can be used as matrix are Bis Phenol A, glycidyl methacrylate and urethane dimethacrylate. However, the former one is used in most cases. In terms of fillers, glass fiber is extensively used owing to its ability to reduce wear damage and transparency. Besides that it also helps in reducing the shrinking observed due to polymerization of the resin composites along with the reduction in the thermal coefficient expansion which can cause mismatch between the modulus of the resin and teeth (Zhou *et al.*, 2019).

(2) Dental post:

Dental post is known as pins, which are used in the case where teeth cannot maintain filling due to the absence of the adequate structure. conventionally they are manufactured using metals and alloys (nickel chromium, aluminum, platinum, titanium and stainless steel) which resulted in corrosion fracture, less retention due to higher modulus of dental post as compared to dentine (Machado *et al.*, 2017). Keeping in view of all the requirements newer dental post were fabricated using polymer composites, which not only decreased the fracture rate but also reduced the stress at dentine, which is root cause of post loosening. The composite material involved in manufacturing dental composites are polyester matrix reinforced with short glass fiber and epoxy matrix with unidirectional carbon fiber. Fig. 6 presents a dental post of a restored tooth.

Introduction

Additive manufacturing (AM) initially used a polymer substrate for the production of parts. However, as the research continues, metals and ceramic composites became substitutes. These materials are used to support the progression, not to give the anticipated product in AM. For example, various polymers are adapted for different roles as adhesion promoters, plasticisers, and surfactants in fused deposition modelling (FDM) (Tofail *et al.*, 2018; Oladapo *et al.*, 2020d,e; Oluwole *et al.*, 2020; Zahedi *et al.*, 2013, 2019). Layered production, commonly referred to as AM, is a sophisticated manufacturing technique that adds layered material in subset to create three-dimensional (3D) products, using computer-aided design (CAD) models. The most significant benefit of AM is that it eliminates complex manufacturing processes when it comes to geometric complexities and elements that cannot be created with subtractive manufacturing processes. In many studies, various AM processes' operating principles are preserved and mostly used categories, depending on the starting material's condition. Table 1 shows the material working principle for AM presenting process types, layer technology, and conventional materials (Bikas *et al.*, 2016; Umme *et al.*, 2016). The complicated concepts and working principles of electron beam melting (EBM), selective laser melting (SLM), fused deposition modelling (FDM), selective laser sintering (SLS), stereolithography (SLA) and multi-jet modelling (MJM) are subsequently discussed.

The application of modern technology in AM requires materials containing a mixture of traditional ceramics, ceramics, or unusual properties that are not found in polymers. The blended materials synthesise new materials, using two or more materials with desired properties to produce the final product's expected properties and characteristics. Combining various materials to form each component's desired properties could initiate different AM research challenges and opportunities (Oladapo *et al.*, 2019a,b; Tafaoli-Masoule *et al.*, 2019; Li *et al.*, 2017; Ahn *et al.*, 2012). The basic requirements to address these challenges are developing standardized national testing centers to test and improve the AM method. These testing centers could be challenged with the responsibility of developing design and testing policies for AM. Although the finite element analysis (FEA) adopted for the AM primary process analysis and testing is considered an acute phase. The development of modelling and simulation tools for AM technology software cost modeling and new production planning manuals for vehicles, biomedical space and space has currently been investigated (Oladapo *et al.*, 2018a; Jiang *et al.*, 2013). These are to ensure that research, development, and trade produce new material that combines unusual characteristics to produce advanced and complex consumer products. Therefore, monitoring the use of AM technology with composites and nanocomposites have

Table 1 Analysis of the state of materials and working principles of various AM processes

State of materials	Process	Layer creation method	Typical materials	Applications
Powder	EBM	Electron beams scanning	Metal	Tooling, functional parts
	3D Printing	Drop-on-demand binder printing	Polymer, metal, ceramic, other powders	Prototypes, casting shells, tooling
	SLM	Laser scanning	Metal	Tooling, functional parts
Filament	FDM	Continuous extrusion & deposition	Thermoplastics, waxes	Prototypes, casting patterns
	Robocasting	Continuous extrusion	Ceramic paste	Functional parts
Liquid	SLS	Laser scanning	Thermoplastics, waxes, metal & ceramic powder	Prototypes, casting patterns, metal and ceramic
	SLA	Laser scanning	UV curable resin, ceramic suspension	Prototypes, casting patterns
	MJM	Inkjet printing	Acrylic plastic, wax	Prototypes, casting patterns

Fig. 1 AM technological steps for polymer matrix composites.

become research of necessity. Moreover, there are few ways products are produced by AM technology with various prototypes, concepts, and functions proposed by many systems over the last 30 years.

Stereolithography (SLA) depends on the solidification of the liquid photopolymer, using an ultraviolet light intensity beam to form a two-dimensional layer line (Oladapo *et al.*, 2018b; Ioana *et al.*, 2018). After completing the first layer, the construction platform moves in the z-direction to create a new photopolymer coat. There are laser sintering, laser melting, fusion forming, multiple electron beam jets, rolling object production, and 3D printing of plaster (Oladapo *et al.*, 2020a,b,c; Exner *et al.*, 2007). A laser-shaped liquid is formed by the deposition of formed metal and 3D impression per head of inkjet powder. There are many ways to implement and deploy AM in the industry. Some of these include small-scale economic production, ecological sustainability, component functionality, and geometric freedom. Research and commercialization of AM technology and materials are now one of the primary fields that have been investigated in the last decay (Kumar, 2009; Vaucher *et al.*, 2002). AM has many essential applications in automotive, aerospace, energy, biomedicine, bone implant, and other areas. Fig. 1 shows the order of phases of AM technology from the abstract design to the implementation stage. There are many requirements of AM technology in several active areas. For example, studies on research aimed to investigate AM technology through different types of composite materials for bone implant have been conducted (Oladapo *et al.*, 2019b; Slocombe and Li, 2001) the importance of biomedical engineering. These research include: (1) verification of the physics and properties of AM models, (2) adapting health products to improve the health of the population, (3) apply monitoring techniques, such as sensors to measure and monitor AM operations and (4) increase demand-to-demand efficiency by simplifying the supply chain system.

However, there are various AM techniques, but some are used to develop composite materials. The processes used to make composite materials are necessarily laser selective sintering or fusion modeling network. In some AM techniques, the fiber-reinforced compounds were produced. AM techniques mainly used in fiber-based compounds are SL, FDM, and SLS. Considering suitable powder-based techniques, such as rapid prototyping (RP), the blend is made into soft powder, challenging to extract the fibre layers (Hon and Gill 2003; Cheung and Gibson 2002). It is worthy of note that the inclusion of short fibres in the process is complicated, and the use of prolonged or continuous tissue is limited only by SL (Srinivas *et al.*, 2009; Shishkovsky and Tarasova, 2001). AM processed FDM and Laminated Object Manufacture (LOM) strips of suitable filament fibre-reinforced composite, as a precursor before, require laminated materials. Therefore, it must be formulated and developed.

AM Applications

The addition and improvement of the printed products' value-adding characteristics are seen as good benefits in employing AM technology. This section subsequently explains the most common products made using AM technology in diverse areas (Alexandre and Vogt, 2004; Oladapo *et al.*, 2019c).

Fused Deposition Modeling

FDM can produce durable composites by melting some or all the fibres formed from the raw material, creating a link between the layer and the continuous layer. There should be a removable wax support structure in protruding parts, using the second nozzle to deposit the support materials. The development of raw materials for FDM production is essential. The filament of the raw material must have sufficient composition, strength, and low viscosity. The base polymer, which consists of basic polymers, plasticisers, and surfactants and other metals, polymers, and ceramics, is forced out like a filament through the nozzle during the process. Glue is usually applied to the base plate. The glue is a solution to increase the surfactants' adhesion and elasticity, increase the flowability, and permit homogeneous metal distribution as the build-up progresses. The filament development requires the proper mixing of these components, which give a useful ability for a bone implant (Yu and Schaffer, 2009; Czyzewski, 2009).

The main reason for treating composite materials on a single element is facilitating the liquid phase sintering process using different materials to obtain the alloying materials' inaccessible properties. The first type of copper (Cu) acts as a molten liquid during the Process and contains SLS Fe-Cu bound to the Fe powder to form Fe-Cu compounds. The development of mechanical properties or other properties of steel products is similarly possible. The formation of common compounds using another type of SLS/SLM process is carried out by adding hydroxyapatite (HAP) to polycaprolactone (PCL) to form PCL/HAP through SLS to increase resistance and biocompatibility and use for a bone implant (Klosterman *et al.*, 1999; Zhan, 2001). The production of such composite materials in the SLS/SLM domain, using the three methods is discussed in the following section.

Composites Production

The most surprising application is forming a polymer matrix composite (PMC), and the coupling mechanism is a blended and incinerated liquid phase invasion, polymer, and ceramic powder. PCL and HAP, polyetheretherketone (PEEK), and HAP (Oladapo *et al.*, 2019c; Karalekas, 2004) (Fig. 2) and monotonic polymethyl methacrylate (PMMA) have been used to generate a laser, and they show the best combination of powder. However, powder coatings are used for biocompatibility (Adeoye *et al.*, 2017; Gupta and Ogale, 2004). There are also other advantages of powder coating, in the case of nano- Al_2O_3 and - pressure-sensitive nanoparticles compound Al_2O_3 to avoid the accumulation of the nanoparticles to provide the particle dispersion and coated with pressure-sensitive adhesive (PSA) tape. The appropriate polymer matrix is used as a doping agent, instead of reinforcing it. This is so because it forms fibres in the presence of the challenge of a loose powder layer (Zak *et al.*, 2000; Balogun and Oladapo, 2019). A stirred auxiliary powder polymer's density and strength are not suitable for maximizing the powder particles' use. The dust can be used for glass powder coated polyamide (PE), aluminium powder, and high-density polyethylene (HDPE)/HA-coated will help each particle to correct the problem and compound components that are distributed to the final products. However, when the powdered ingredients are fibers, production problems arise (Cijun Shuai *et al.*, 2020; Selvam *et al.*, 2020). In this method and with a ceramic matrix of carboxymethylcellulose (CMC), metal matrix (MMC), (used in the preparation of materials in general), ceramic products and SLS metals do not produce deposition due to the quality of products and change in the material compositions (Ashish *et al.*, 2020; Florina *et al.*, 2019). For solid materials, such as PMC (for complete cure), the powder mixture is added to additional materials or filtered porous products. The addition of LaCO_3 to WC-Co and Cu components helps to reduce internal stresses build-up of the material. Surface strength strengthens both products, and Green CO can be obtained by the infiltration of bronze (Park *et al.*, 2017; Florina *et al.*, 2019). Fig. 2 shows a fabrication process and technique adopted for 3D-printing and testing of PLA, HAP, and PEEK for biomedical applications. Table 1, as previously presented, summarizes the materials directly employed by SLS DuraForm Customers fiberglass and synthetic, and the Form AF (fiber), has many specific compounds, synthetic, and Aluminum added to their composition (Rebelo *et al.*, 2017; Shuai *et al.*, 2020).

Fig. 3 shows a fabrication process for the development of smart soft composites and a 3D-printed morphing structure for phone/robot.

Composites of In-Situ Reactions and Furnace Treatment

Laser-induced chemical reactions are used to produce particles on-demand in SLS. The energy from this system by the laser beam can be used in two different ways: (1) to overcome the start energy of the reactants during the reaction stages and (2) to form chemical compounds during the mixed reaction. In-situ formation and uniform distribution of enhanced wetting compounds are better than the sclerosis of compounds to release exothermic energy contributing to the chemical mixture. Examples of the first type are the formation of TiB_2 and MMC supplemented with TiC in a mixed powder of Cu, Ti, and B_4C (Isakov *et al.*, 2016; Czyzewski, 2009). The second type is, for example, a self-leveling high temperature (SHS) synthesis of TiC-A1203 in a compound of TiO_2 , Al, and C, CuO, and Al are compound of Al_2O_3 -Cu and NiTi-HA is a composition of NiTi and HAP. The chemical reactions can also contribute to forming a binder in treatment with SiC laser, decomposing the SiC, and then reacting Si_2 with the O_2 gas connected to the remaining SiC powder (Srinivas *et al.*, 2009). A sintering treatment in a laser oven is another way to prepare a compound where the furnace can be used. Before opening the furnace or after penetration, the chemical reaction of the furnace and infiltration, which is an example of first type sintered acrylic laser glass, is processed in an oven that dissolves the acrylic binder and the glass in the ceramic apatite and mullite phase of $\text{fSiO}_2\text{AlO}_3\text{-P}_2\text{O}_5$ partially substituted CaO-CaF_2 ceramic compound (Kurimoto *et al.*, 2015; Motealleh *et al.*, 2018).

In this case, the compound was prepared using an oven cycle without filtration, and Al furnace was filtered with a sintered laser coated with SiC powder polymer to form the MMC. Other examples include the higher melting temperature of Cu-Mo formation of the compound at a high temperature of ceramic superconducting, which has guanine, In_2O_3 , and the infiltration of SiC (Shemelya *et al.*, 2015; Oladapo *et al.*, 2020a,b,c). The second type, the most common, is the formation of Si/SiC compounds.

Fig. 2 3D-printing and testing techniques of PLA, PHA, and PEEK for biomedical application. Reproduced from Rebelo, R., Fernandes, M., Figueiro, R., 2017. Biopolymers in medical implants: A brief review. *Procedia Engineering* 200, 236–243. Florina, D. Cojocaru, V.B., Popa, M.I., Lobiuc, A., Verestiuc, L., 2019. Biopolymers – Calcium phosphates composites with inclusions of magnetic nanoparticles for bone tissue engineering. *Int. Jou. of Bio. Macromol.* 12515, 612–620.

Laser treated SiC is treated with a phenolic resin. After curing in the furnace, the resin causes the carbon with a part of the infiltrated Si's made to react to form SiC and finally produces the Si-SiC compound. The amount of SiC in the compound can be controlled by transforming the green product with the phenolic resin. Another example of a chemical reaction located in a furnace is nitrogen gas that reacts with the Al alloy's green product to form AlN. Then, the MMC is made by licking with the Al alloy. The Al compound production with force depends on nitride formation in the nanostructure (Kalsoom, 2016; Castles and Isakov, 2016).

Fig. 3 Patient cells harvesting and culture Fabrication process for developing smart soft composites 3D-printed morphing structure of solvatochromic sensor for organ production.

Polymeric Products

Production of polymer products with AM is called high-speed sintering (HSS). The main application of polymers by AM is the production of polymer prototypes used for visual verification and assembly approval. The polymers can also be used in biomedical applications through compatible and biodegradable polymers. Compatible biopolymers can be used in external and internal applications in the biomedical field. The hearing aid sector is an example of an appeal globally because of the hardness and durability of the polymer materials used (Isakov *et al.*, 2016; Feng *et al.*, 2019). An example of internal use is a lumbar tissue graft with cardiac graft and microscopic internal cavity. Polymeric materials are also used in art and jewellery projects, as they are used for vacuum leak modeling.

Furthermore, one of the best metal applications of AM technology is the AM motor design. The general concept of mould manufacturing can produce more complex free-form cooling channels than the heat holes obtained from drilling. AM technology's application generally ensures consistent heat transfer and adjustable heat dissipation (Hwang and Reyes, 2015; Perez *et al.*, 2014). Usually, it is used for laser or electron beam applications, especially during the production of images. Hybrid, ready-to-shape shapes are easy to add, save time, cost, and enhances processing capabilities. In addition to using metal to create LS, it has a more detailed profile, especially in biomedical areas of bone structure, which are essential applications. Also, computed tomography (CT) speeds up general biomedical products and not through conventional methods, such as scanning, modifying, converting to STL files, cutting, and production, which are more comfortable. Another advantage is reducing operating time (Saravanan *et al.*, 2016; Kokkinis *et al.*, 2015). Fig. 4 shows an example of computed tomography in the biomedical field, as previously presented.

The metal AM has three different material processing categories, depending on the AM method, building volume, and power source. These categories include bedding systems, power distribution systems, and wire feed systems, shown in Fig. 5. Another classification of the AM metal process depends on the method of binding the metal particles. For example, the Direct Metal Deposition (DMD), fabrication processes, as shown in Fig. 5. The examples of things used in AM mixed processes are SLS, 3DP, FDM, and SLA, while SLM techniques used models for LMD and CPA (Martin *et al.*, 2015; Zhong *et al.*, 2001). From Fig. 4 it can be observed that composite AM technologies can be classified based on the composite materials available for specific application/production and its tendency for further development. Also, Fig. 5. shows the classification of metallic powder that can be adopted and currently in use for AM processes.

Standards for Polymers Testing

The American society for testing and materials (ASTM) standards for plastic testing include ASTM D638 for tensile testing. Examples are the tensile test of a dumbbell-shaped specimen in the thickness direction. During this test, the general properties are tensile strength, elasticity, rupture flexibility, and elasticity modulus. ASTM D412 is designed for tensile testing of vulcanized rubber and thermoplastic elastomers that could be adopted for AM (Ning *et al.*, 2015; Love *et al.*, 2014). The ASTM D882 standard includes tensile the sting for thin plastic films. Also, ASTM D3039 covers the extension properties of polymer matrix composite materials reinforced with high modulus fibers. The international organization for standardization (ISO) developed the ISO 527

Fig. 4 A summary of the AM technologies and their composite materials for application/production.

standard to characterise plastic traction. The ISO 37 standard also deals with obtaining the tensile properties of thermoplastic and vulcanized rubbers (Saravanan *et al.*, 2016; Feng *et al.*, 2018). ASTM D790 addresses the determination of flexural properties, including flexural strength and plastic flexural modulus. There are two methods used to determine these characteristics: Method A is for materials that are broken by small deviations, while Process Up is for elements with significant differences (Chen *et al.*, 2018; Lian *et al.*, 2019). ISO 178 deals with the method to determine the flexural properties of rigid and semi-rigid plastics. Also, this pattern provides the parameters of flexural strength and flexural modulus. The ASTM D1938 covers the standard for determining a plastic film or film's tear resistance or film of comparable thickness. This standard does not apply to fragile plastics. ISO 34 has ISO 34-2: 2015; this refers to the breaking test standards for small samples and ISO 34-1: 2010 for angled traction, crescent, and pants. ASTM D695 covers the compression test of hard plastics, and the obtained properties include the compressive strength, modulus of elasticity, yield stress, and tension, in addition to the yield strength. The deformation rates used are relatively low (Rizwan *et al.*, 2017; Sadeghzade *et al.*, 2017) for ISO 604 used as the test model. The ASTM D256 for Izod impact test and ASTM D6110 for Charpy impact tests measure plastic samples' impact resistance with pendular hammer notches. International Standard Organization also has similar standards for impact test samples for Izod and Charpy impact tests. ASTM D7791 covers the measurement of the fatigue properties of plastic materials under uniaxial loading. In general, universal test machines are used for this method. ASTM D3479 deals with tensile fatigue tests of polymer matrix composites (Ning *et al.*, 2015; Sun *et al.*, 2017).

Nanocomposites

It has been elucidated that more concern is vital to produce composite materials in a single process cycle. This is one of the possibilities of additive technologies to meet the above requirement in using nano-moulding structures of building materials. It has been confirmed that the composite structure of 3D nanomaterials has many applications in chemical and biological environments. For instance, SLS has the advantage of producing functional components of metal connections with less labour, time, and skills to produce the geometry of internal states or complexity (Raz *et al.*, 2018; Ain *et al.*, 2017). The effect of SLM process variables is investigated by the microstructure of the components produced due to nano-carbide, titanium carbide (TiC) production fields for general properties, and metallurgical mechanism. It is formed without sufficient laser energy or interlayer; the condensation reaction is limited for a small extension in a lens stored in the Ti6Al4V + 20% TiC/Ni.

Fig. 5 Classification of metallic powder used in additive manufacturing processes.

Thermogravimetric and spray drying processes are new techniques that combine nanocomposite coatings with the flow characteristics required to meet the requirements. As shown in Fig. 6, additive nano-manufacturing (ANM) can select different materials and have more flexibility in the project. Examples include immersion lithography techniques: ANM, dip-pen nanolithography (DPN), magnetic hydrodynamic jet clip (MHD), optical tweezers, and electrokinetic nanomanipulator. The primary variable, ANM, has a minimum value and a choice of process rates. Materials comparison of several technologies: It was concluded that the mechanical properties, thermal and electrical conductivity, sintering temperature, and nanocomposite access could be increased by studying ANM properties' AM technique, as shown in Table 2. In every method, AM still faces some obstacles (Lin *et al.*, 2018; Oladapo *et al.*, 2020a,b,c; Cui *et al.*, 2020).

The printing's combination attracts rough surfaces on the printed parts and nozzle clog during the printing process. In other words, the method for determining the processing, synthesis patterns of nanomaterials and processes is not sufficient (Oladapo *et al.*, 2020a,b,c; Lian *et al.*, 2019). One nanocomposites fabricated through AM technology is nanocomposite TiC/Ti, using the SLS effects and the nanoscale type. The structural properties of SLS fabricated TiC/Ti include microstructure condensation, mechanical, and nanocomposites. Using mixed nanoparticles and TiC/Ti, it can then be summarized, as coated with mechanical and nanocomposites, then covered with coated TiC/Ti. Essential factors affected the concentration. The laser has a maximum power of 0.33 kJ/m. TiC/Ti nanocomposite, which focuses on microstructure, was added to the TiC of the nanostructures. SLM is responsible for the morphology of the density and SLM nanoparticles, maybe a relatively dense microstructure of the susceptibility process. The TiC, 0.22, and 2.8×10^{-6} m low laser friction coefficients can be additional parameters, due to the high-intensity wear rate (Love *et al.*, 2014; Oladapo *et al.*, 2018a)

Structural Composites

Periodically, titanium and titanium cell structures with a wide range of biomedical applications require the production of computer-aided design/manufacture (CAD/CAM) layers in EBM processing techniques used in medical-grade production

Fig. 6 SEM and the relative nanostructure processes of computational 4D printing of CMC and its composite.

Table 2 Comparison between different ANM technological features

Method	Material	Resolution	Speed
EHD	Metal nanoparticles, polymers, block copolymers	10 nm	80 mm/s
STM	Single atoms (e.g., Xe)	Atomic	<1 nm/s
DPN	From small organic molecules of biological polymers and form colloidal particles to metal ions and sols	50 nm on polycrystalline surfaces, 15 nm resolution on single-crystal surfaces,	Increased with the number of probes.
DLW	Polymers, metals	65 nm, 22 nm	100 lm/s
AFM	Single atoms of nano-scale object (CNTs, nano-particles)	Atomic	<10 nm/s

Note: EHD, STM, DPN, DLW and AFM represent electrohydrodynamic, scanning tunnelling microscopy, dip-pen nanolithography, direct laser writing, and atomic force microscopes, respectively.

substitutes. Due to the need for real-time conditions, titanium cell structures' mechanical properties are suitable for medical applications. To study the scaffold's feasibility and performance, it was produced in one step using both a laser powder and a wire feed. The materials used in this study are copper powder and nickel wire for the accumulation of copper/nickel/iron structure in H13 tool steel - the distributions of elements related to the morphology, microstructure, appearance phase. They are examined under a scanning electron microscope (SEM), spectroscopy, energy distribution (EDS), X-ray diffraction (XRD), and scanning electron microscope. Cu-Ni precipitation at a second powder approves with gradients and sedimentation functions. Another important concept that has been developed is mixed metals. The laser deposition process has a significant advantage, in that a puddle of fusion is formed after the laser, which makes it very convenient to coat the layer by alloy. This characteristic allows for separate composition properties for each level. Traditional methods hinge on localised thermal treatment, but laser deposition (LD) allows the installation and assembly of hardware freely through computer models, resulting in controlling the internal structure's composition. This research is most useful in studies of metal metallurgy and alloy development. **Fig. 7** shows the design of the ear and a composite graduated alloy during LD processing.

The functionally graded material (FGM) suggests the opportunity to regulate the arrangement and enhance the installed part's properties. FGM has many potential applications. Possible FGM examples; thermoelectric and dielectric classes are piezoelectrically classified materials, grade composite electrodes, and tungsten-copper compounds. **Fig. 7**. Shows a representation of 3D interweaving of biology and electronics via AM to generate a bionic organ and 3D bioprinting process from the design stage to control deposition module. With three different head of tissue for human organ, the 3D model is generated from the patient's medical image using computer tomography for precision Multi-Cathedral. materials, AgNP infused silicone for the bionic ear and 3D printer for the printing process illustration of the 3D-printed bionic ear (Jiang *et al.*, 2013; Shuai *et al.*, 2020).

Metal or metal-ceramic FGM, SLM technique, and laminated objects can be done by laser coating or high solidification. It can be done using printing processes by polymer-polymer or polymer-ceramic, ceramic-ceramic, inkjet printing, SLS, or 3D (Shuai *et al.*, 2020; Selvam *et al.*, 2020). One technique used to produce fully dense structures through functional classification is laser deposition, where various compositions are injected. Nanocomposite-based FGM also has sufficient potential. For practical grade nanocomposites, the 3D structure is fabricated using free-form fabrication based on SLS fabrication. In this study, nanocomposite nylon-11/silica is prepared using different volume fractions of the fumed silica nanoparticles of 15 nm in the range of 0%- 10%. The hardness is between 17.8 and 19.2 GPa and is slightly below the boundary between adjacent layers. The upper surface's

toughness increase is due to the transition phase from t-ZrO₂ to m-ZrO₂ during the lower surface fracture. One of the FGM studies focuses on the Al and Cu coupling of stainless steel plates, using ultrasonic consolidation (UC) bonding techniques. The optimized layer sequence is adopted, and it is found that the optimal sample 62 had a 200-sheet width and a 1300-length. The optical microscopy card shows that UC FG Musing is successfully produced. In this study, the final recommendation to improve the FGM production process using UC is to adopt the processing strategy or use an intermediate layer (Sadeghzade *et al.*, 2017; Isakov *et al.*, 2016). With EBM metal processing, dense and porous dusty titanium structures are produced to meet the aesthetic and functional requirements of patients and surgical patients.

Laser Net Shaping

Laser Network Modeling (LEM) is similar to SLS because it is a powder and laser technology. More than two critical steps attract the accumulation of dust. The production of composite materials in the laser engineered net shaping (LENS) is similar to SLS lasers and powder's reaction. The lenses can be dust-free. Lenses are used to form compounds having different strengths and produce FGM, using different powders. Also, in composite LOM fibre-reinforcement, there is an example of the production of a fibre-reinforced composite (FRC) film of 0.5 mm fixing the layers of ceramic strips with pre-prepared fibres. The fiber preparations are made by connecting a unidirectional continuous fiber to a thermosetting resin (Vaucher *et al.*, 2002; Rizwan *et al.*, 2017). Continuous ceramic fibre cutting with CO₂ laser is damaged during the LOM process due to combustion heat and adjacent polymers. The problem can be avoided using a copper vapour laser because the fibre is disturbed by the photoelectric mechanism. The LOM product is also developed by linking the cellulose fiber pyrolysis filter paper to adhesive tapes developed from phenolic resins, polyvinyl butyral, benzyl tantalate paste containing butyl and ethanol. The phenolic resin is changed to carbon by producing the pyrolyzed part under nitrogen at 800°C. Porous carbonized samples were then filtered through liquid Si at 1500°C under vacuum to produce FRC (Kumar, 2009; Feng *et al.*, 2019).

SLS and FDM of Fiber-Reinforced Composites

Among all the AM techniques, selective SLS laser sintering is frequently used with short fiber, continuous fiber, and fibre mats in FRC. The choice of fiberglass instead of ceramic or carbon fiber reduces ultraviolet rays' opacity, which is very suitable for SL technology for FRC production. Although continuous filaments are ideal for improving mechanical properties, shorter fiber mixtures with higher aspect ratios have similar properties (Du *et al.*, 2019; Pourhaghgouy *et al.*, 2016). An increase in the volume leads to an increase in the functionality, but it is limited and attracts additional challenges after creating and processing the scene. However, coating the fibers helps to reduce the viscosity of the mixture. The grains also bind between the layers partially in an area not encapsulated in the first layer. Uneven lengths, random alignment of components, and fractures during mixing are possible. Table 3 summarizes some materials used to produce FRC in SLS (Karalekas, 2004; Slocombe and Li, 2001).

Composites for Biomedical Applications

Using the AM technique, scaffolding is used in dental implants to form lean racks and continuous biopolymers. Moreover, it is used to produce ceramics with RP. These compatible compounds are bioactive, biominerals, or at various levels of biological adsorption. Biodegradable compounds stand out as new materials incorporated into tissue engineering, because: (1) no other surgical procedures are required to remove implants after treatment, and (2) less risky mechanical properties between bones and implants (Oladapo *et al.*, 2019b; Park *et al.*, 2017). Therefore, 3D printing techniques for membrane separation is possible through

Table 3 Additive Manufacturing Processes

various methods, as depicted in Fig. 8. AM presents the following unique advantages in conventional building techniques: it explains more about its approval, considering shape and size, freedom, and spherical pore formation. With no toxic binders or solvents, accuracy, and repeatability, various sizes and shapes are few parameters required to create RP-racks, using traditional techniques (Rebelo *et al.*, 2017; Oladapo *et al.*, 2019c).

AM creates necessary local pores to create a potential field for tissue growth in general techniques, creating a prescribed global protozoon. Central follicles are used to disperse food, blood flow, and fluids and control cell growth and tissue differentiation. The addition of Ca-P ceramics to polymers forms compounds. Better adhesion behavior of similar bones and untreated polymers is obtained. Calcium phosphate increases the biodegradability of composites. HAP increases the bioactive polymer compounds without causing brittleness. In the case of PEEK/HAP contents, the correct amount of HAP is approximately 40%. Bioactive crystals and ceramic cups are other fillers needed for the HAP polymer (Oladapo *et al.*, 2019b; Park *et al.*, 2017). Dental implants made of titanium, titanium (99 NiTi), and HAP are fabricated via SLS, with combined powder HAP and NiTi throughout the SLS mechanism. It is well synthesized. Both flex sensors and “glove” have been 3D-printed, as described in Fig. 9, to establish AM technology's versatility further. LOM is also used in individual implants, consisting of layers of calcium hydroxyapatite compressed with 125 to 150 ml of glass and calcium phosphate. The size of the pores of the LOM implants depends on the size of the HAP, and it can be increased by eliminating large particles. Table 4 presents the materials used to produce various biocomposites, using different AM techniques (Oladapo *et al.*, 2020a,b,c; Florina *et al.*, 2019). Fig. 9. Represent a Flex sensor Design process and 3Dprinted sensor to undergoing mechanical stress and glove to respond to change by flexing Emerging flexible sensors based on nanomaterials of recent status and applications and Ammonia-sensing ability of differently structured hydroxyapatite blended cellulose (Lian *et al.*, 2019; Zak *et al.*, 2000).

Concluding Remarks

This study presents an AM technology study focused on a review of developing composite materials with new production technology. Various performance characteristics are presented to demonstrate the importance of AM rather than traditional production techniques. Almost the principal performance characteristics of the study of physical and mechanical properties, such as relative density, tribological properties, and the nature of the developed microstructure, were considered applicable. The composite material was reviewed for AM techniques for mechanical and bioengineering applications. The usefulness of other interdisciplinary applications such as optics, electronics, and thermal are also studied in detail. There is a need to develop AM techniques, such as searching for a new AM technique to increase the UC/SLM machine's capacity or improve the field of application. SL has great potential for the continuous production of fiber-reinforced composites. Also, additive nanocomposites and nanoparticles are presented, discussing the methods and properties of the manufacturing additives. One of AM's most effective composites is the functionally graded materials FGM analysed in this study. They offer the ability to control the composition and optimize the properties of the formed part. However, techniques for quick and accurate repeatability should be given more consideration. SLS and 3D printing can produce on-site ceramics for the compound formation and give a chance to advance the differentiated field for future research. Developing a particular post is the easiest way to make compositions using SLS and 3DP. In particular, the production of bio-composites for the manufacture of scaffolds is an area where AM has significant advantages over conventional techniques and will attract more attention in the future with its current development rate. Conclusively, opportunities, challenges, and the future direction of AM are provided as an essential step in disseminating this creative production technique in various sectors, especially in biomedical applications.

Introduction

Hydrogel, a class of DDs, are classified as 'intelligent' drug-delivery responsive to pH, temperature and other physiological, and biochemical factors (Mahinroosta *et al.*, 2018; Mo *et al.*, 2020). These gels are comprised of vast polymeric networks to absorb large amounts of water without being dissolved. Composite hydrogels of marine polysaccharide (MP) origin, such as ulvan (Tziveleka *et al.*, 2019), gelatin (Rodríguez-Rodríguez *et al.*, 2020), alginate (Fernando *et al.*, 2020), chitin (Shen *et al.*, 2016), carrageenan (Yegappan *et al.*, 2018), fucoidan (Fitton *et al.*, 2019), agarose (Zarrintaj *et al.*, 2018), chitosan (Rodríguez-Rodríguez *et al.*, 2020), and chitooligosaccharides (Park *et al.*, 2018) are well studied. Natural polymers that are vulnerable to enzymatic degradation, or synthetic-polymers, having hydrolysable moieties, have been used to make hydrogels. Out of all the hydrogels, marine polysaccharides obtained from natural sources are of prime importance due to their low toxicity, degradability, and biocompatibility (Cardoso *et al.*, 2016; Kuznetsova *et al.*, 2020; Laurienzo, 2010; Lee *et al.*, 2017).

The discovery of a variety of active compounds was thought to be potential candidates for therapeutic purposes but only a few are successful. Low 'bioavailability' and the rate at which a drug reaches the target tissue are the two main factors leading to the poor activity of the therapeutic compounds (Li *et al.*, 2019; Stuurman *et al.*, 2013). The decrease in bioavailability can lead to decreased plasma concentration of drugs hence, requiring re-administration. This increases the chances of overdose. The controlled drug delivery systems (DDs) are used as an alternative for the regulation of bioavailability of the therapeutic agents (Li *et al.*, 2019). In such systems, the drug is allowed to release in a controlled fashion by incorporating the active therapeutic-agent into the polymeric matrix. The time for drug release may vary from hours to months or years. Drug carriers have been studied as natural or synthetic polymers containing hydrophobic and hydrophilic components. But DDs come with the price of certain limitations like manufacturing costs, time constraints, and toxic byproducts. To make 'intelligent DDs', researchers have strived to regulate the functionality, biodegradability and environmental response of the DDs by studying their physical as well as chemical characteristics (Talebian and Foroughi, 2020; Zhang *et al.*, 2020a). Other traits like electrostatic charges, ionic interactions, and multiple functional groups have made marine polysaccharide quite a significant polymer in delivering genes, metals, peptides, proteins, antigens, and drugs. The preparation, physicochemical properties, and applications will be briefly discussed. And various classes of MP-hydrogel composites will be further described in the article.

Marine Polysaccharide Hydrogel Composites

Polymeric networks containing a large number of hydrophilic groups are cross-linked with each other to form hydrogels. Due to the presence of physical and/or chemical bonds between the polymeric chains, they do not dissolve in the water despite having a high affinity for it. The soft and rubbery texture of the fully-swollen hydrogels resembles with living tissues. It reduces irritation to the surrounding tissues, and in between the body fluids and hydrogel surface, minimizes protein adsorption, and cell adhesion (Palmese *et al.*, 2019). And the chances of the negative immune reactions are also reduced. Hydrogels make excellent drug delivery vehicles owing to some of their unique characteristics (Fu, 2019). Muco- and bioadhesive characteristics of these hydrogel composites enhance tissue permeability and drug residence is found in many polymers, for example, PAA, PEG, PVA (Chopra *et al.*, 2020; Hanafy *et al.*, 2019). Due to the inter-chain bridges and mucous glycoproteins, they demonstrate adhesive-property.

Chitosan is unique from other marine polysaccharides due to the presence of nitrogen in its molecular structure and capacity to form polyelectrolyte-complexes (Islam *et al.*, 2017). It does not encourage an immune response (Foster *et al.*, 2015). As chitosan is biodegradable, non-toxic, and can also be sterilized, these properties make it a great excipient, perfect for the release of therapeutic agents in a controlled way. They are extremely versatile materials with a wide range of applications in the biotechnological and biomedical fields. Ahsan *et al.* developed a chitosan-based composite hydrogel cross-linked with glutaraldehyde and loaded with I-131 and tested in a breast cancer xenograft mouse model (Ahsan *et al.*, 2020). The result showed a decrease in the tumor progression rate and prevented more than half of the tumor recurrence and metastatic spread.

Carrageenan (car-) are comprised of linear sulfated polysaccharides isolated from the species of Rhodophyta (Patel, 2012; Shukla *et al.*, 2016). These polysaccharides and their derivatives have been exploited in cosmetics, foods, and pharmaceuticals. Car- are exploited in the drug delivery system as a controlled release agent that possesses antioxidant properties as well (Genicot *et al.*, 2018; Li *et al.*, 2014). There are three variants of car- i.e., lambda, kappa, and iota, that possess a range of properties such as biocompatibility, biodegradability, mechanical strength, hydrophilicity, and stability (Derkach *et al.*, 2018; Ghanbarzadeh *et al.*, 2018; Sahiner *et al.*, 2017). Car- composite films in combination with glycerol and citric acid further ameliorate the anti-microbial activity (Khare *et al.*, 2016; Sedayu *et al.*, 2019).

Covalent Interactions of MP-Based Hydrogel Composites With Drug/Metal

Owing to the porous structure of the hydrogels, the metals/drug, through physical mixing, is removed from the hydrogel. The rate of the chemical and enzymatic-cleavage of the polymer-drug bond is controlled by covalently bonding the drug to the hydrogel-matrix (Li and Mooney, 2016). This covalent interaction may result in delaying the release of drug from a few weeks to months. The sustained release of paclitaxel was observed by the help of a thermosensitive-polyphosphazene-paclitaxel conjugate gel (Chun *et al.*, 2009). Osteogenic differentiation of human mesenchymal stem cells was facilitated with the conjugation of dexamethasone to the photo-reactive mono-acylated PEG (Briggs *et al.*, 2009). The daunomycin cross-linked to poly-(aldehyde guluronate) (Bouhadir *et al.*, 2000) was released based on the hydrolysis-rate of the drug-polymer covalent-linkage ranging from two days to six weeks.

There are two easy ways to do the drug/metal loading of the hydrogels, one way is the cross-linking diffusion of the active agent into the hydrogel pores and the other is how in the presence of a drug, macromolecule, or proteins cross-linking of the polymeric chains is done (Akhtar *et al.*, 2016). The initial hydrogel swelling resulted in bursting and a typical drug-release of 70% occurred but by the use of cross-linker, the loss was reduced to about 10%–25% (Zhang *et al.*, 2020b).

Micro-/Nanocapsules and Interpenetration Networks

The drug-containing micro- and nanocapsules can be incorporated into the hydrogels. For example, the encapsulation of TGF-beta1 loaded gelatin-microparticles within the biodegradable polymer oligo-(polyethylene glycol fumarate) gel can help control the release of the TGF-beta1 over the period of one month (Holland *et al.*, 2003). The drug-release of dexamethasone with Chitosan hydrogel composite was slowed down by approximately 6% versus PVA-based hydrogels encapsulated-with steroid loaded microspheres (Long *et al.*, 2019). Researchers have now dispersed microparticles containing drugs in the hydrogel-matrix without affecting the swelling as well as the hydrogel network. As the hydrogel continues to degrade, the drugs and proteins that have been encapsulated are released and then they diffuse to the outside medium.

The strength of polymers can be increased by interlacing two or more polymeric chains together. The cross-linked MP-network expands into monomers of the polymer. These monomeric subunits are polymerized and form a physically intertwined network called an interpenetrating network. They are arranged in such a way that one polymer remains at rest state while the other runs through it in a cross manner, e.g., semi-IPN polyether, silk, PVP, etc.

Hydrophobic Interactions of Hydrogels

One class of hydrogel-systems is the thermo-reversible hydrogels, which have been engineered by researchers, function (by depending on environmental temperature) in the formation of transient gel or liquid states. Flowable liquid-solution is used for junction production between chains by yielding semi-rigid gel due to the property of such polymers that use hydrophobic-interactions or secondary bonding to their advantage. When the temperature of the system goes beyond the lower critical solution temperature (LCST) then the material converts from hydrophilic to hydrophobic (Klouda and Mikos, 2008). Polymer solution has importance in biomedical applications due to its property of having decreased viscosity plus forming gel above a LCST. These are injected in the body as a liquid that forms gel when the body temperature exceeds LCST. This acts as transporter matrices for a broad variety of biomedical as well as the pharmaceutical applications (Mahinroosta *et al.*, 2018; Mo *et al.*, 2020). Invasive surgeries are not required and delivery of agents to a defected-site without significant negative-effects for introducing these injectable, gelling systems. Negative effects may be the use of organic-solvents or the formation of toxic-byproducts. Custom produced scaffold designs have been eliminated by the use of injectable hydrogels.

The collection of co-polymers is based on chitosan hydrogels which in solution demonstrates gelation neutralized with polyol salts (Liu *et al.*, 2016). This method is used for the mixture of glycerol-phosphate-disodium salt (GP) and chitosan that is sensitive to temperature. At 37°C room temperature, the gel-mixture remains a clear liquid.

An injectable thermoreversible gel was developed by a few scientists (Bhattarai *et al.*, 2010) that utilized chitosan for gelation. Chitosan PEG co-polymers (made by Schiff base and sodium cyanoborohydride by chemically-grafting monohydroxy-PEG on the backbone of chitosan) were used for the preparation of gel. By balancing the ratio of hydrophilic and hydrophobic-groups the co-polymer goes from the injectable-solution at room-temperature to the gel at body temperature via a thermo-reversible route. The passage of the gel solution is temperature-dependent. At approximately 25°C there is an increase in viscosity of hydrogel. Below the temperature at which transition occurs, injection of the solution with a needle of 22 G can be done. This is further created into a transparent gel by the complete transformation. This occurs above the transition temperature. High temperature promotes hydrophobic interactions between polymer chains, while at low-temperature H-bonding takes place between PEG molecules, hence resulting in the creation of gel (Hu *et al.*, 2019; Ranganathan *et al.*, 2018). Some other derivatives of cellulose with hydrophilic moieties also possess such thermo-sensitive gelation (Kabir *et al.*, 2018).

Many other hydrogels have been prepared and formulated with the use of co-polymers combined with poly(N-isopropyl acrylamide) (PNIPAM) as well as poloxamers which have dominant hydrophobic-interactions at high temperatures (Burdukova *et al.*, 2010). In reversible hydrogel formations, such polymers make appropriate candidates. Precipitation of PNIPAM solutions takes place above the 32°C. H-bonding between the polymer and polar-molecules results in the polymer-dissolution at low

temperatures. Dehydration of hydrophobic isopropyl groups leads to the creation of gel at a higher temperature. This process takes place at some stage in the coil-to-globule transition. For the regulation in temperature of gelation closer to physiological temperatures in order to improve the mechanical-strength and advance the bio-compatibility of the hydrogel, PNIPAM has been adapted with many natural polymers (Lanzalaco and Armelin, 2017). Deliverance of peptides, drugs, cells, and proteins rapidly in the body (by injection) can take place by the use of these formulations when these agents are integrated or mixed with the dissolved polymer. The controlled release system is provided by the gel which is formed in the process. Polymers like poloxamers, triblock copolymers as well as PEO-PPO-PEO develop hydrogel when the concentration of the polymers is retained beyond a critical value, and the temperature is above the polymeric-LCST (Klouda and Mikos, 2008). These polymers also have a central hydrophobic-segment which is joined with two regions that are hydrophilic in nature. Chitosan-poloxamer solution was verified as an injectable delivery vehicle due to its solution-gel transition which was $\sim 25^{\circ}\text{C}$ (Varshosaz *et al.*, 2008).

Physical Association Networks

Two conditions must be satisfied by the MP-polymeric network to satisfy requisite hydrogel composite features. Firstly, strong inter-chain interactions are required for the development of semi-permanent junctions in the molecular-network. Secondly, in the polymer network, the water molecules should have access and residence, promoted by the network. Non-covalent strategies are utilized to prepare the gels that meet all the above-mentioned demands and they capitalize on hydrophobic; H-bonding and electrostatic forces present in between the chains of polymers (Fu *et al.*, 2018; Picchioni and Muljana, 2018). Ionic, poly-electrolyte, inter-polymer complex, and hydrophobic-associations (major physicals interactions) are present in these MP gels. The formation of gel can also be reversed as these are pure physical interactions. Also, tunable gel swelling behavior can be achieved if the nature and concentration of the second component of the fabrication process are adjusted. Chitosan-based physical-gels have a short life span of some days to almost about a month in physiological media; by mixing various components under appropriate conditions, these can be prepared. As a result, for short-term drug-release applications, physical gels make a good source. Gelatin does not require any toxic covalent-linker-molecules (Jătaru *et al.*, 2013), so it is safe for a clinical application as it is but it has poor mechanical strength and uncontrolled dissolution due to which they have limited applications (Ahmadi *et al.*, 2015).

Physical Mixtures and Secondary Bonding

Polymer-blends between MP and other water-soluble nonionic-polymers can also result in the formation of hydrogels. These polymer mixtures form inter-polymer complexations or crystal-junction points due to lyophilization and a freeze-thaw process (Parhi, 2017). The cross-linking sites of hydrogels are formed due to this interaction between the chains. In the case of PVA-polymer, when the negativity of chitosan is increased, the formation of PVA crystallites is affected. Hence, less ordered structures of hydrogels are developed. A composite of chitosan and polyethyleneimine (PEI) (Lu *et al.*, 2014) is widely used as a gene transfection agent. 3D hydrogel was produced within five minutes when PEI was mixed with alginate-hyaluronic for tissue repairing (Rajaram *et al.*, 2015).

Chitosan-chitosan self-associations take part in holding the gel structure together. At pH 7.5, chitosan is insoluble and crystallite formation occurs because of this between its chains. Chitosan alone can also be used for hydrogel formation, without the need to add any other polymer or complexing-molecule, as shown by Ladet *et al.* (2008) by the process called as hydro-alcohol gel creation. Sodium hydroxide solution could be used to neutralize the amino-group of chitosan and the process of gel creation depended on it. H-bonds, hydrophobic-interactions, and chitosan-crystallites were formed by prohibiting ionic-repulsion between the polymer chains. Observations included hydrogels macroscopic shrinkage during gel depletion and neutralization. Multi-layered onion-like hydrogels were prepared with the gelatin (Ladet *et al.*, 2011). This gelation method was not constant which could help in the encapsulation of drugs and their delivery.

Ionic Complexes

The chitosan can interact with the molecules that are anionic in nature while car- can interact with cationic molecules. Between small negatively charged molecules and chitosan, ionic-complexes of mixed charged systems can be prepared (Ahmadi *et al.*, 2015; Moura *et al.*, 2011) or between the negatively charged metals like Pt (II), Pd (II), and Mo (VI) (Nie *et al.*, 2016). The charge density of the negatively-charged agents and their size determines the hydrogels owning a variety of material-characteristics that can be obtained upon these ionic-interactions. The concentration of chitosan-polymer and degree of de-acetylation also determines the same. Chitosan is bound through its protonated amino-groups and this is done by small molecules as well as anions. While, on the other side, instead of the electrostatic-interaction, the metal-ions form a coordinate covalent bond with the polymer (Ahmadi *et al.*, 2015; Nie *et al.*, 2016). The bonds found in anionic-molecules and the polycation are weaker than this strong bonds. The global charge-density of small molecules is affected due to environmental pH and pKa. Whereas, the charge density of metal anions is independent of pH. There is very little or no charge at all above the pH 6 in chitosan; it has a pKa ~ 6.3 , so its use is reduced under physiological conditions. To attain strong ionic interactions, high charge density must be present between the anionic molecules; their MW should also be very small so that they can easily diffuse through the polymer matrix for the quick and faster formation of electrostatic bonds. Other secondary interchain interactions also contribute to ionic complexation. The

H-bonding present between the ionic-molecules and the hydroxyl-groups of chitosan could be one of the interactions or it could be the interaction between the post-cationic charge neutralization interaction between the de-acylated chitosan chains (Foster *et al.*, 2015; Islam *et al.*, 2017). Such interactions take part in modulating to state distinctive material properties, like pH sensitivity and enhancing the physical properties of hydrogels.

The brittleness and the rigidity of the κ -gels could be reduced by blending it with either λ - or ι - (BeMiller, 2019). κ - works opposite to ι - in terms of reactivities to K^+ and Ca^{2+} salts. ι - can form a relatively stronger and stable gel as compared to κ - with Ca^{2+} salts, which do not bleed (syneresis), soft and resilient. The gel is thawed and frozen without damaging the texture. The syneresis could be prevented by blending λ - with κ - (Zia *et al.*, 2017). The ι - demonstrates thixotropic behavior in aqueous solutions while κ - does the same in milk. The gel of κ - is weak but fine particles of a material can be suspended e.g., chocolate milk and cocoa. The gels of the car- are thermo-reversible in the range of 40–70°C depending upon the presence of cations and concentration. ι - gels are lucid while the κ - gels are cloudy. But the hard gel is better for flavor release making κ - the superior in this regard (Loret *et al.*, 2009; Zia *et al.*, 2017). The acidic pH tolerability and stability of κ - is poor and in the range of 4–10 but by adding other car- it may help in building the pH tolerance. The solubility of λ - is more in cold 50% sugar solutions as compared to ι - (insoluble) and κ - (soluble only in hot solution). The λ - addition in syrups is preferable (Loret *et al.*, 2009). λ - and ι - are soluble in 10% salt solutions whereas κ - is insoluble. Freeze-thaw stability is absent in κ - but present in ι - and λ -. The gel texture could be improved by the addition of ι - (BeMiller, 2019). κ - forms brittle and stiff gels whereas ι - forms elastic and soft gels, so by combining these two gels the overall texture could be improved (Zia *et al.*, 2017). At 20°C, all salts are soluble in λ -, but $[Na^+ \text{ salt}]$ is only soluble for ι - and/or λ -. In cold milk, the ι - and κ - are insoluble but λ - thickens it. κ -, ι -, λ - individually can play wonder in the food and pharmaceutical industries but their blends give them a set of overtly improved unique characteristics (Ghanbarzadeh *et al.*, 2018). By pairing ι - and κ -, the gelatin alternative could be achieved. There is a synergy with starch of ι - and absence of κ - and λ - with locust bean gum but absence in case of λ - and ι - (Tang *et al.*, 2021). Shear reversibility is not present in κ - but do present in λ -, and ι - (Torres *et al.*, 2017; van de Velde *et al.*, 2005). The "melt-in-your-mouth" the sensation is given by ι - unlike κ - that gives hard and brittle to soft and brittle textures depending upon the concentration. κ - with λ - are used for bodying in syrups. κ - and ι - are used as an alternative to gelatin (BeMiller, 2019; Blakemore, 2016). κ - and λ - could be used in the preparation of suspensions. λ - and κ - could be used for emulsion stabilization. λ - do not need any ions whereas κ - and ι - need K^+ and Ca^{2+} to form a viscous solution whereas λ - do not need any ions (Blakemore, 2016). ι - and κ - are used for mouthfeel and texture. Fat stabilization can be achieved with the help of ι - and λ -. All three car- can use as a binder, emollient, and to prepare suspension/dispersion. The difference in properties of the car- depends upon the position and number of ester sulfate groups. The more the ester sulfate groups present in the car-, the lower the temperature of solubility. It also contributes to gel inhibition in λ - while lower gel strength in ι - and κ - (BeMiller, 2019). But by the addition of cations, the dispersion increases consequently increasing the temperature of gelling, re-melt, and dissolution of car- (Blakemore, 2016).

Polyelectrolyte Complexes (PECs)

Polyelectrolytes do develop electrostatic-interactions with marine polysaccharides although the ionic-molecules present in the ionic-complexation are very different from the polyelectrolytes (Ahmadi *et al.*, 2015). The polyelectrolyte-chitosan interaction is much stronger than the other types of interactions like the van der Waals as well as H-bonding. These complexes have great advantages. No catalysts, reactive agents, or organic precursors are used for their complexation. PECs have a simple and reversible complexation as they only contain chitosan and polyelectrolyte. Chitosan-based PEC networks are prepared with the use of negatively-charged water-soluble macromolecules (Jana *et al.*, 2014), the negatively-charged synthetic-polymers, and proteins (Peniche *et al.*, 2018). The stability of the compounds is determined by the strength of the ion, the density of the charge, solvent, temperature, and pH (Ahmed, 2015; Lin and Anseth, 2009; Peniche *et al.*, 2018). Ionic-interactions as well as the PEC hydrogel-properties are regulated by the pH of the environment.

The uses of the car- are also underpinned by their metal-binding capabilities. The 3, 6-anhydro-bridge and degree of sulfation cause the three car- to selectively bind with various metal ions and demonstrated different rheological properties (Cao *et al.*, 2018). κ - having one negatively charged sulfate group prefer monovalent cations and selectively binds to Cs^+ , Rb^+ , and K^+ but not with Na^+ . ι - binds selectively with Ca^{2+} due to the presence of two sulfate groups (Covis *et al.*, 2016). λ - (three sulfate groups) do not bind with Cr^{3+} but bind with Al^{3+} and Fe^{3+} (Running *et al.*, 2012). This is because of the different properties of metal ions, different ionic hydration, and electrostatic interactions with the car- (Salman *et al.*, 2020). These monovalent and divalent ions reduce the repulsion of κ - and ι - helices resulting in stabilization. λ - do not form helical structure due to the 4C_1 conformation and absence of 3, 6-anhydro-bridge ring thus does not form gel. The metal-binding properties of the pure car- were reported in a study for divalent and trivalent metal ions (Khotimchenko *et al.*, 2010) while we reported the blends of κ - with ion-exchange resins for Cu^{2+} sorption (Salman *et al.*, 2020).

Cross-Linked Networks

Even without the addition of cross-linkers, the physically-bounded hydrogels are capable of gel-formation, yet there seem to be certain drawbacks. As it can lead to inconsistent performance in vivo due to difficulty in controlling the functioning of chemicals, pore sizes, and degradation of physical gel. Permanent hydrogel networks are directly produced by *chemically cross-linking* through

linking covalent-bond between the polymer-chains. For the production of chitosan $-NH_2$ and $-OH$ chemical-handles as well as cross-linker, are utilized. This also includes the formation of different numbers of other linkage chemistries. The other methods of network formation include small molecule cross-linker, polymer-polymer reaction, or enzyme-catalyzed reactions.

He *et al.* developed the light or photo-sensitive chitosan hydrogel within situ with the help of functionalizing the polymer with an acid group ($-N_3$) $[COO]$ (He *et al.*, 2017). Gelation is caused when the azide group is exposed to sunlight; it is changed into a nitrene group. The thermo-sensitive, chitosan-pluronic hydrogels are developed and are cross-linked by UV sunlight (Park *et al.*, 2009).

Enzymatic cross-linking is an extra-ordinary technique use in biomedical applications and in-situ hydrogel formation. Horseradish peroxidase (HRP) B-type hemoprotein composed of a single chain which is used to catalyze reactions associated with cross-linking. Jin *et al* used the chitosan derivatives that were water-soluble such as glycolic acid to produce chitosan-based with HRP and H_2O_2 that were injectables (Jin *et al.*, 2009). In gelation, varying the polymer concentration, water contents of gel, enzymatic degradation, and mechanical properties can be modified according to requirement, and also gelation time can be varied by polymer concentration. Enzymes, Tyrosinase, involves in the hydrogel in situ as it is an oxidizing agent used in gelation. Tyrosinase oxidizes the tyrosyl to quinone which forms intermolecular linkage (Jin *et al.*, 2014).

Drug Loading and Release

The hydrogel composites for DDs depend on the physical and chemical properties of the gel. And the choice of hydrogel materials network arrangement and drug loading method must be made to complement the properties of the drug (i.e., hydrophobicity, charge) and its mode of action (sustained drug release versus rapid, high exposure). Three major drug loading approaches are (1) Diffusion, (2) Entrapment, and (3) Interaction. Each method has advantages and disadvantages and should be chosen after careful observation of the hydrogel network used and the nature of the drug. The drug release from a hydrogel can occur in one of three different modes. (1) Diffusion, (2) Chemical/environmental stimulation, and (3) Enzyme specific stimulation.

Chitosan shows the pH-sensitive behavior of weak polybasic nature dissolving easily at low pH. To take advantage of this phenomenon, PEC hydrogels dissolved in the stomach have been prepared to change the charge balance inside the hydrogel causing swelling of PEC complexes (Ahmadi *et al.*, 2015). The swelling of hydrogels in the stomach is limited but triggered in the intestine due to further changes in pH. In one example, ionically cross-linked succinyl-chitosan (suc-chi)/alginate hydrogels showed release of as little as 11.6% of nifedipine at pH 1.5 and as much as 76% at pH 7.4 after 15 h (Dai *et al.*, 2008). This particular polyelectrolyte complex was made sensitive to higher pH due to a large number of carboxylated groups in the network. This conclusion suggested that the suc-chi/alginate hydrogel bead could be a potential polymer carrier in the intestinal area for drug delivery. Berger *et al.* had observed several different PEC systems based on chitosan (Berger *et al.*, 2004). pH-sensitive chitosan-acrylamide-grafted hydroxyethyl cellulose (AAM-g-HEC)-based semi-IPN hydrogel microspheres were prepared for the release of pH-sensitive drugs, i.e., slower release at pH 1.2 and faster at 7.4, explaining their potential drug release application in the GIT tract (Ahmed *et al.*, 2009). If the hydrogel expresses thermo-responsive behavior then the drug release form such as IPN is further affected by temperature (e.g., PNIPAM-chitosan) (Burdukova *et al.*, 2010). In addition to PEC and IPN networks, polyblend-based hydrogels also exhibit pH sensitivity. If the mixing part is neutral and hydrophilic (polarized and capable of H-bonding), such as PEO and polyvinylpyrrolidone (PVP) under acidic conditions, chitosan's primary amine is protonated, causing repulsion in the chain and subsequent swelling or breaking up (Patel and Amiji, 1996).

By incorporating the magnetic particles into the cross-linked MP hydrogel, a typical magnetic field sensitivity can be achieved. So, a chitosan-based nanocomposite hydrogel composed of chitosan and montmorillonite, a nanohydrogel exhibiting an exfoliated nanostructure under electro-stimulation was reported (Haerudin *et al.*, 2010). The main mechanisms of drug release from the electro-responsive hydrogels include drug solution ejection during deswelling, diffusion, changed drug electrophoresis, and electro-induced gel erosion.

Car- blends for the Tolterodine L-Tartrate controlled release by simple physical mixing. They reported that the carrier behavior changes with different combinations of car-. Also, the release rate was slower for the pure car- but by incorporating λ - along with other car-, controlled release formulations were obtained (Nanaki *et al.*, 2010). While the water barrier, mechanical (Rhim and Wang, 2013), and electrolytic properties were obtained through the preparation of ternary biohydrogel blends of agar/ κ -car-/konjac glucomannan and kappa/cellulose derivatives (Dafe *et al.*, 2017). In another study, λ - and ι - blends were effective matrices for sustained release formulation of fluvastatin. Higher dissolution profiles were obtained for physical mixtures of car- and drug as compared to their corresponding complexes (Karavas *et al.*, 2014). The biodegradable film with an antioxidant barrier, and pH-responsive properties was obtained by blending *Prunus maackii* extract with κ -car-/hydroxypropyl methylcellulose. κ - was blended with carboxymethyl cellulose for the effective delivery of *Lactobacillus plantarum* (Dafe *et al.*, 2017). The car-/alginate based hydrogels were reported recently for the lidocaine controlled release (Rasool *et al.*, 2020).

Conclusions

Due to the ease of fabrication, gelation, and chemical structure, the MP based hydrogels are quite attractive biomaterials. These gels may have tailor-made porosities, mechanical strengths, and dimensions that can be developed to support their area of application.

Notably, in this article, we saw how the distinct ionic characteristics of car- and chitosan can offer even wide latitude to biomaterial engineers in the types of hydrogel composites that can be developed, and the processes by which they fragment and deteriorate in the body. In "smart" delivery systems the flexibility of these MP as a major component is compounded by its biocompatibility and in-vivo biodegradability. MP has received significant attention in the development of injectable, in-situ gelling systems for tumor treatment, tissue regeneration and as a delivery vehicle in oral and ophthalmic systems. We consider these current advances will produce delivery systems of the next generation as we gain a greater understanding of the dynamics of mixed MP-chain networks. We will be capable of adapting these materials for different metals and drug formulations, release conditions. Cheap, non-toxic, environment friendly and efficient MP-hydrogel composite systems can move closer to clinical availability once these design parameters have been set.

Introduction

The current unparalleled boom in the field of material sciences has never been witnessed in the known history of humanity. The industrial revolution and the many feats achieved in different avenues of life have only been possible due to the continuous innovations in the development of unique materials, their manufacturing, processing, and identification of unconventional combinations with various properties. Polymer matrix composites are a class of materials that have been the keystone of this revolution. A material blend made by the dispersion of one or more physically and chemically distinctive constituents into a polymer matrix is termed as polymer matrix composite and could be called multifunctional polymer matrix composite if it possesses additional properties than those of the main matrix former alone (Curtis, 1996). These composites have also been loosely called intelligent or smart materials. The dispersant component or filler is usually scattered in the form of fibers, tubes, capsules or particles in a continuous polymer matrix. The choice of dispersant components and the processing treatments during the blending process guide the emergence of the so-called multifunctionality. Furthermore, size, shape, and arrangement of the discontinuous phase is pivotal in the scope of multifunctionality.

Initially, polymer composites were designed to achieve the ability to withstand maximum load for structural purposes (non-functional) in the fields of civil and mechanical engineering. The functional attributes (non-structural) were then incorporated with the aid of specific devices. This not only compromised the structural features but also led to underperformance of the functional devices. The maintenance of such equipment or structures was hectic and time consuming thus leading to a hefty increase in overall cost. The emergence of multifunctional polymer composites allowed the integration of various functional features in the structural materials without any substantial gain in the structural mass or loss in their mechanical prowess (Christodoulou and Venables, 2003). The structural traits of an ideal multifunctional polymer matrix composite include ability to bear passive load, durability, malleability and resistance to deform upon sudden or continuous exposure of thermal, mechanical, chemical, or biological stresses (Ali and Andriyana, 2020). Whereas, a range of functional characteristics can be included such as thermal, electrical or sound insulation, flame retardation, energy generation and storage, electromagnetic interference shielding, self-repairing, sensing of mechanical or chemical phenomenon, ability to control contamination, and biocompatibility and biodegradability for health monitoring, drug delivery, antimicrobial activity and wound healing applications.

This article is an effort to concisely describe the various functionalities of these useful materials along with nature, properties, and maneuvering of the fillers that give rise to the desirable traits. In addition, the latest striking findings in the key applications of the multifunctionalized polymer matrix composites have also been discussed.

Insulation Functionality

Electrical Insulation

The scale of size has significantly moved towards the lower numbers in the past few decades for the high-end application electronics, thanks to the excellence in materials research. This downsizing structural trend has facilitated unprecedented growth in many industries, such as computation, telecommunication, transportation, energy storage, renewable energy generation, civil and mechanical engineering, and warfare. However, the race to miniaturize the appliances has led to crowding of various functional electrical or electronic parts in limited dimensions. Electrical insulation of the parts is needed, in order for such systems to be functional. The use of polymeric composites is quite popular in devising such parts as the polymeric matrices are usually less conductive to electrical and thermal energies. Nonetheless, due to thermal insulation and poor heat dissipation of the simple polymeric composites, there arises the problem of overheating. Overheating, if not dealt with, can lead to short-circuits, unreliable performance, reduced operational life, and high maintenance cost.

Significant efforts have been made to develop the multifunctional polymer composites with thermal conductivity with electrical insulation properties. Different kinds of conductive fillers have been tested in polymer composites for thermal conductivity. Use of metallic or inorganic materials as fillers was considered as the natural choice, but, the degree of dispersion of these fillers within the polymer matrix is difficult to control due to poor filler-matrix interaction. The weaker interaction at the interface of metallic fillers and matrix polymers causes filler aggregation and raises the interfacial thermal resistance, thus, leading to sub-optimal thermal conductivity performance of such composites. Raising the filler levels in the overall composition of composites can overcome this issue but will compromise the electrical insulation and mechanical strength of the composites (Guo *et al.*, 2020).

Carbon based fillers (carbon/graphene nanotubes) possess excellent conductivity properties and have also been applied for improving the thermal conductivity of the polymer composites, but, they also have good electrical conductivity, making them less

desirable for such applications (Song *et al.*, 2019). Modification of carbon nanotubes could help in improving their electrical insulation attribute. Fluorinated carbon nanotubes when grafted with poly (methyl methacrylate) showed better dispersion within the matrix of the polymer, reduced interfacial thermal resistance and better electrical insulation (Wang and Wu, 2019). Techniques used for designing anisotropic nanofillers-based electrically insulated polymer composites with better thermal conductivity create materials with heat flow in one direction only, hence, limiting the overall efficiency of the composites. Polymer matrix composite containing 3 D polydopamine coated graphene oxide structure as filler was shown to possess electrical insulation and the ability to dissipate the thermal energy in all planes. The 3D construct ensures lower interfacial thermal resistance by minimizing the polymer/filler interfaces (Yuan *et al.*, 2019).

Boron-nitride, in the form of nanoparticles, nanosheets, nanotubes or nanoribbons, has emerged as an excellent nanofiller for thermally conductive polymer composites. Other than thermal conductivity, boron nitride is also resistant to mild acids and corrosion, and provides minimal friction; making it as a suitable material for filler in polymer composites (Li *et al.*, 2020a; Zou *et al.*, 2019). On the other hand, higher loading of boron-nitride as a filler are required for the desirable thermal conductivity. Use of multiple fillers or hybrid fillers than a single filler could be a more viable option in dealing with heat dissipation by electrically insulated composite materials. Combinations of boron-nitride with other fillers such as carbon based materials or glass fibers have been reported to improve the thermal conductivity of polymer composites while maintain the required level of electrical insulation (Ohayon-Lavi *et al.*, 2020; Tang *et al.*, 2019; Zhang *et al.*, 2019).

Thermal Insulation

In contrast to the electronics industry, thermal insulation is highly desirable for construction, machine performance, goods storage, transportation, and packaging purposes. Currently, the governments are striving to make thermal insulation as an integral part of the construction industry to conserve energy. The global realization about the hazardous ecological outcomes pertaining to the use of fossil-fuels for energy generation has been the driving force for the design of efficient thermal insulator materials. Thermal insulation is also desirable for personnel safety, proper storage and transportation of thermolabile goods, medicine or biological samples (Verma and Singh, 2019; Aditya *et al.*, 2017; Chatterjee and Pandey, 2003).

The highly porous polymeric composite constructs having high mechanical strength and lightweight, such as foams, are desirable for the thermal insulation. Recently, carbon nanotubes enforced polypropylene composites-based foam showed higher mechanical strength with better control over pore structure for better thermal insulation (Zhao *et al.*, 2020). Decrease in thermal insulation capability of the foams at higher temperature stress makes them unsuitable for special purposes. Polymer composite aerogels, air filled polymeric composites, are durable, light-weight and have greater thermal insulation capacity even at higher temperatures. Inorganic filler cross-linked polyimide aerogels demonstrate tunable cell structure linked to the degree of cross-linking, increased mechanical strength, and persevered thermal insulation at elevated temperature (Fan *et al.*, 2019). Carbon-based materials (carbon nanotubes or graphene fibers) have high mechanical strength but good conductivity properties therefore their use in thermal insulation material is less than desirable. Use of natural fibers as fillers in the foams rather than the carbon based fibers is more beneficial as natural fibers are cheap and possess inherent thermal inertness, lower densities, and porous structure along with reasonable mechanical strength (Floreana and Manea, 2019).

Thermal aging, reduction in performance of thermal insulation materials over a period of time, is needed to be addressed in the design of the advanced polymeric composites. It can originate from the changes in the nature of material due to damage to the polymer construct, porous structure shrinkage, hygroscopicity, microbial degradation or biodegradation of the natural fibers, and leakage of entrapped air or gasses from the aerosol cells (Fraleoni-Morgera and Chhikara, 2019; Takagi, 2019). Generally, material strength and durability are compromised by the addition of various fillers (Charles *et al.*, 2020).

Noise Reduction

The facilitation and the luxurious life style owing to the industrial growth has introduced many detrimental factors into the daily lives of the current era. One of such factors is the uncontrolled and unwanted noise generated from industrial machines, construction work, automobiles, aeroplanes, and ships. The health threats of noise have been considerable, and it is even recognized by the world health organization. These effects include but not limited to auditory malfunction, cardiac issues, central nervous system disorders, and behavioral changes (Goines and Hagler, 2007; Stansfeld and Matheson, 2003). The deleterious effects of noise have also been evident in different animal communities (Senzaki *et al.*, 2020).

Traditionally, glass have been extensively used for the acoustic control in buildings. However, polymer composites have been investigated for noise reduction purposes. Degree and nature of porosity (granular, cellular, or fibrous) of the composite plays an important role in the reduction of noise amplitude. Polymer matrices supplemented with high density minerals, glass fibers, carbon nanotubes, graphite platelets, and natural fibers show promising noise reduction properties (Chuang *et al.*, 2016; Berardi and Iannace, 2015). The length of the fibers, size of the nanoparticles or platelets, filler microstructure, orientation of fibers, and the overall filler content in the polymer composite influence the extent to which a certain type of noise can be reduced (Kumar *et al.*, 2020).

Inclusion of high density fillers such as minerals in the polymer composites reduces the vibration in the material due to greater mass, thus, reduction of noise is possible from such composite systems. Increased noise reduction is also related to the higher degree of dispersion of the dense minerals within the polymer matrix (Ersoy, 2020). However, dense materials increase the mass of

the final product which is considered undesirable in various applications. Insertion of glass fiber felt in the form of multiple layers in the polymer matrix generate more voids which ensures better sound absorption (Xue *et al.*, 2019). Similarly, entrapment of air within the glass fiber reinforced polymer matrix dampens the sound better than the one without air bubbles (Shin *et al.*, 2020).

Natural fibers or by-products of crops have marvelous noise dampening potency (Kolya and Kang, 2020). Now-a-days, the use of natural materials or by-products is being emphasized in construction industry for industrial waste management and encouragement of use of renewable resources to attenuate the impact of synthetic materials on the environment. The nature of the fiber and its size has major impact in the sound dampening potential of the polymer composites made with these renewable sources (Marques *et al.*, 2020a,b; Tiuc *et al.*, 2019). Including multiple fillers in the polymer matrix gives better noise reduction than the polymer composites with a single filler (Kim *et al.*, 2013). Combination of natural and synthetic fillers in the polymer matrices are beneficial for acoustic application due to the lower costs and better mechanical and structural properties (Gokulkumar *et al.*, 2019; Prabhu *et al.*, 2019).

Vibration Damping

Vibrations are a serious cause of harm for both structures and machines. The integrity and durability are affected on prolonged exposure of vibrational energy. Whereas, performance and experience or comfort of mechanical, electronics, or transporting vehicles are markedly downgraded by the vibrations. Passive damping of vibrations by use of materials is considered cheap and doable rather than using active damping by specific devices (Chung, 2001). Viscoelasticity of the materials is considered important factor for designing damping materials (Zhou *et al.*, 2016). Metals, glass, carbon based material, and natural fibers have been employed to make damping polymer composites (Tang and Yan, 2020).

Slip-stick phenomenon of carbon nanotubes within the polymer matrix was identified as the mechanism of efficient damping by carbon enforced polymer composites (Ajayan *et al.*, 2006). This effect is more prominent when the nanotubes have abysmal interaction with the polymer matrix. Recently, Joy *et al.* (2020) showed that inner oscillations of the multiwalled carbon nanotubes within the polymer composite depends upon the nanoscale architecture affect the damping efficiency. The graphene nanoplatelets enforced epoxy polymer composites also displayed better vibration damping potential (Rafiee *et al.*, 2019). Use of piezoelectric metal wires in tandem with carbon nanotubes in matrix composite were demonstrated to dissipate the vibrational energy more efficiently by additional conductivity phenomenon (Groo *et al.*, 2019). The renewable source, good viscoelasticity, and hollow nature of natural fibers also make them suitable for use in vibration absorbing matrices (Takagi, 2019).

Flame Retardation

Direct or indirect fire accidents are the most common and dangerous threat to the life, environment, machines and structures. Despite the multidimensional usefulness of the polymer composites, these materials are most vulnerable to fire due to the hydrocarbon or petrochemical origin (Bar *et al.*, 2015). The flammability of the polymeric composites, once initiated, is a self-sustaining attribute. Polymers are prone to degradation or pyrolysis in the presence of sufficient heat and oxygen; subsequent release of the flammable gases further promotes the extensive burning of material by exploitation of the available oxygen, thus, strengthening the overall cycle (Babu *et al.*, 2020). In order to impart flame retardancy, fillers are used that can improve the heat tolerance of the polymer matrix or reduce the emission of inflammable gases or increase the formation of char (a non-flammable byproduct of combustion formed along with gases), or release the gases that are non-flammable (Bar *et al.*, 2015).

Carbon nanotubes or graphene fibers are inherently non-flammable and have good heat tolerance, but, fire events usually produce high heat levels, so requiring further modification of the material to improve the fire retardancy. Use of phosphorous modification is useful in improving the fire retardancy of graphene enforced polymer composites by improving thermal endurance, increased char formation (non-flammable byproduct of combustion), and decreased smoke generation (Cao *et al.*, 2019). Use of magnesium hydroxide as anti-dripping agent (materials that decrease the flow of the polymers upon heating) in the carbon fiber reinforced phosphorous modified polymer composites was reported to significantly amplify the fire resistance of the designed composites (Javaid and Afzal, 2018). Layered double hydroxides have been shown to improve the flame retardancy of the polymer composites by improving thermal resistance, promoting emission of non-flammable gases, and making a carbonized layer (Luo *et al.*, 2020). Recently, it was demonstrated that fire resistance of the intumescent flame retardants (thermoreponsive agents that form a flame and heat-resistant swellable carbon layer) by inclusion of metal oxides (Gao *et al.*, 2020). Metal organic frameworks as fillers are also gaining significant attention due to their ability to limit the spread of fire by forming char barrier, absorbing the pyrolysis products, and suppressing the toxic and flammable gases (Pan *et al.*, 2020).

Energy Harvesting, Storage, and Conservation

Energy Generation

The massive energy generation in the last century by burning fossil fuel has caused significant ecological disturbances to conclude that the future of humanity and earth is at stake. This realization has been continuously spreading across the globe to curb the

consumption of hydrocarbons in every aspect of life and has fueled the search for the generation of energy from the more natural processes. Solar, wind, magnetic, tribological, electrostatic, and piezoelectric and many more phenomenon are being explored aggressively in this regard (Bai *et al.*, 2018).

The use of polymeric composites is increasing in the recent studies for efficient harvesting of energy. Graphene as a carbon based conducting material possesses interesting properties and has been used in the form of sheets for the polymeric photovoltaic cells. Different modification approaches have been used to further enhance its applications (Tiwari *et al.*, 2020). Thermoelectric harvesting has also been recently studied with graphene based hybrid polymeric composites owing to the good conductivity of graphene (Liu *et al.*, 2020). Due to the boost in demand of wearable gadgets, search for the elastic polymer composites for thermoelectric harvesting is also increasing. Biomedical monitoring of diseases by use of miniature electronics is pushing the horizon of material development. Brittle polymers can be functionalized into more elastic and adaptable structures for such applications (Kim *et al.*, 2020). Piezoelectric energy harvesting (converting vibrations or mechanical energy into electricity) by polymeric composites incorporating metal organic framework have been investigated for the self-sustainable monitoring of the arterial pulse (Hadavi Moghadam *et al.*, 2020). Similarly, metal oxide nanoparticles in tandem with multiwalled carbon nanotubes incorporating polymer matrix film as an energy harvester on cardiac pacemaker has been studied (Xu *et al.*, 2020).

Energy Storage

Storage of energy is as important as the energy harvesting from various renewable source. Poor energy storage has been the bottle neck for the development of energy sector in recent years. Polymer composites have been applied for the energy storage devices as batteries (chemical energy storage devices) or capacitors (electrical energy storage devices). However, the use of fillers for efficient energy storage is possible in quantities that downgrade the structural performance of the polymer composites (Chung, 2001). Therefore, the energy storage is quite challenging for the material scientists.

The dielectric layer in capacitor is of prime importance for energy storage as it should be resistant to electrical conductivity and should have amiable interfacial interaction within the conductive polymer matrix. Dielectric polymer composites with sufficient thermal forbearance is key to the success of energy storage (Zhou and Wang, 2020). The layering of the polymer composites with the nanowires of ceramic materials in a gradient architecture showed better control over the breakdown strength and the dielectric properties necessary for the energy storage. The marked improvement in the energy density was made possible by the layered interfacial electric gradient and the barrier sheets to limit the charge leakage (Wang *et al.*, 2020b). The design of polymer composites electrodes for batteries require the interplay of both conductivity and structural integrity. Ionic liquids functionalized polymer composites are also being used as electrodes for batteries (Correia *et al.*, 2020). Graphene nanoplatelets functionalized bimetallic polymer composites when used as electrode in lithium ion battery demonstrate enhanced electrochemical performance due to improved conductivity and shortened lithium ion migration path (Kang *et al.*, 2020).

Electromagnetic Interference Shielding

Dependence of humans on the use of computational devices has rapidly extended from complex devices to the daily life activities. Almost all such electronic machines emit radiations known as electromagnetic waves. Initially, these radiations were identified to interfere with the functionality of other electronics; however, with the every passing day, the deleterious health and behavior effects of these radiations emitted from the excessive utilization of the so-called useful gadgets are coming into light. The ability of the multifunctional polymeric composites to absorb or reflect the electromagnetic radiations has been exploited extensively for electromagnetic interference (EMI) shielding (Chandra *et al.*, 2019). Earlier studies identified that incorporation of short metal fibers in the polymeric coatings for shielding against electromagnetic radiations is useful because of the good adhesion of the coated matrices on the surfaces. The choice of metal depends on the density, ductility, and conductivity (Bagwell *et al.*, 2006). Use of high conductivity fillers in the nanosize range has been preferred and a range of fillers with different attributes have been reported for the EMI shielding in the literature. Greater surface area, higher interfacial interaction in the matrix due to better dispersion, morphological characteristic of filler, and thickness of the shielding material are as important as the nature of the filler (Wanasinghe *et al.*, 2020).

Self-Healing

Nature has always been a source of inspiration for the material scientists to strive for the biomimetic designs or to incorporate features into the materials that exist in the natural settings only. Restoration of a material to its original form, on its own, upon damage from mechanical or thermal stress is termed as self-healing. Although, the natural self-healing in a living organism is too complex, the design of materials is shifting from conventional stress tolerance to the self-repairing (Trask *et al.*, 2007). The self-healing attribute in the polymer composites cannot be achieved without incorporation of stimuli-responsiveness. These stimuli could be mechanical load or impact, temperature, electromagnetic radiations, or light (Hia *et al.*, 2016).

Dispersion of the healing agent filled micro or nanocontainers across the polymeric matrices has been widely employed for the design of self-healing materials. The release of the healing material occurs in response to the stress to restore or minimize the

damage. The containers could be layered to contain the self-healing reactant components within the same container and then dispersed in the polymer matrix. However, the size of such layered containers needs to be minimized along with the residual water content for better restoration of the matrix (Cao *et al.*, 2020a). Double walled capsules have been designed for higher loading of the healing agent to obtain better healing efficiency (Ma *et al.*, 2020). Fabrication of organic coatings of polymer matrix composite containing natural biomass based capsules for healing against scratching and photodegradation of surfaces can be achieved (Qian *et al.*, 2020). Co-encapsulation of reactive liquids or solvents for self-healing could restore the electro-mechanical characteristics of the polymer composites (Zamal *et al.*, 2020). Most of the self-healing materials only restore the structure for limited number of accidental exposures. Increasing the healing capability of the materials in terms of handling of multiple stress incidents could lead to design of self-sustaining structures with least maintenance required. Design of containers with numerous storage units of healing agent has been reported to increase the repeatability of healing phenomenon. The containers are designed to hierarchically release the healing agent layers thus making the material sustainable for multiple healing cycles (Xue *et al.*, 2020).

Other than limited cycles of healing due to the slender healing agent storage capacity, use of healing agent filled containers in the polymer matrix might not yield the effective restoration due to the uneven distribution of these container in the matrix. In addition, after the release of the healing agent, the empty shell of the container could become a structural defect or reduce the efficiency of the overall healing. Shape memory polymers and thermoplastic polymers, alone or in combination, are also being used to make self-repairable functional polymer matrix composites. Jony *et al.* designed a biomimetic self-healing polymeric composite where the shape memory polymer was used to close the cracks, and the thermoplastic polymer induced the healing (Jony *et al.*, 2019). Similarly, thermoplastic poly-caprolactone and shape memorizing polyurethane can fix the impairment in carbon reinforced polymeric composite caused by delamination (Jony *et al.*, 2020). Use of thermoplastic filler layers for healing in matrix composite might lead to generation of voids that can negatively impact the structural integrity or compromise the structure repair. The design of polymer composites where the healing filler reversibly interacts by chemical bonding or other molecular interactions (electrostatic, hydrophobic or hydrogen bonding) with the matrix polymer could lead to a viable self-healing design. Amidated carbon fiber reinforced polymer matrix serves the purpose of the self-repair by hydrogen bonding (Wang *et al.*, 2019). Modified Graphene oxide enforced polymer matrix composite also repairs itself by hydrogen bonding interaction with the polymer matrix (Du *et al.*, 2020). Catalyst-free reversible chemical bonding based self-healing by Diels Alder reaction has been extensively studied. This thermo-sensitive reversible chemical reactions has been applied in various polymer matrix systems including fiber-reinforced plastics, cellulose based composites, polymeric resins, epoxy composites, polyurethane coatings and many more (Cao *et al.*, 2020b; Ouyang *et al.*, 2020; Sahu and Bhowmick, 2020; Shahidzadeh *et al.*, 2020; Wu *et al.*, 2020).

Sensing Functionality

The conductive ability of the multifunctional polymer matrices has been found to respond to various external stress phenomenon, and it can be translated into detecting or sensing the nature and the magnitude of such stimuli. The discrete sensing functionality of polymer composites is crucial for the proper working, maintenance, and mending of the devices or structures (Chen *et al.*, 2020).

Mechanical Sensing

Sensing of strain or pressure from a mechanical stimulus has been applied for the improvements in the transportation industry, civil engineering, robotics, human-machine interface, and health tracking devices. The good dispersibility and filler-matrix interaction yields better sensor performance. Increasing the dispersion and the interfacial interplay of the carbon nanotubes in the thermoplastic polymer by non-covalent interactions increases the sensitivity of the 3-D printed piezoresistive sensors that can detect human motions and stress due to mechanical load (Xiang *et al.*, 2020). Ionic liquids can also be used to improve the dispersion of the conductive carbon nanofillers in the polymer matrix for enhanced intermolecular interactions and more sensitive detection of stress and material deformity (Gariya *et al.*, 2020). Dynamic polymer matrix with a conductive filler that rearranges its network at different strain rates, such as flowy to fixed state, can be used to devise tactical sensors. Such approach uses the fixing of dispersed conductive fillers at the application of stimulus by phase shifting of the polymer matrix, which hinders the conductivity but is regained upon stress removal due to redispersion of the filler in the dynamic polymer network (Zhou *et al.*, 2020). Similarly, dynamic polymer network can be utilized by catalytic conversion of the fixed polymer matrix, which has good sensor functionality even at lower loadings of the conductive segregated nanofiller network (Yuan *et al.*, 2020).

Chemical Sensing

Presence of certain chemicals in the form of ions, vapors, gases, or humidity can be sensed upon their interaction with the smartly designed polymer composites. Chemical sensing is very valuable for detection of warfare chemicals, contamination, biomedical applications, food and pharmaceutical storage, and protection of natural reservoirs. Hydrocarbon soluble polymer matrix functionalized with carbon fibers can detect the presence of the hydrocarbon pollutants originating from leakages or accidents in the petrochemical industry. The interaction of the hydrocarbon material produces structural deformities in the polymer matrix composite and leads to changes in material conductivity (Seshadri *et al.*, 2020). Potentiometric sensors for detection of metal ions was fabricated by inclusion of multiwalled carbon nanotubes in

the lignin-based polymer matrix. Specific interaction of the polyphenolic components of the lignin with the copper ions was attributed to the selective sensing of the metal ions (Gonçalves *et al.*, 2020). Titanium oxide nanoparticles functionalized polyaniline matrix coating was applied to glass-carbon electrode to detect the real-time presence of a harmful industrial pollutant, diaminobenzene (Karim *et al.*, 2020). Polyaniline-multiwalled carbon nanotube hierarchical composites showed high sensitivity detection of low levels of nitric oxide and ammonia gases (Zhang *et al.*, 2020b). Similarly, Cotton fiber-polyaniline multifunctional composites were fabricated for selective sensing of ammonia gas (Zhang *et al.*, 2020c). Humidity detection for sensitive food and pharmaceutical applications is necessary to avoid decomposition of the products. Polymer composite films of polyvinylidene when functionalized with barium-titanium nanoparticles serve as good detectors of humidity based on corresponding changes in the dielectric capacitance (Mallick *et al.*, 2020). Polymer composites for chemical sensing applications are prone to the environment conditions such as temperature and humidity. Moreover, selectivity, competitive interaction of different analytes and sensitivity to detect lower quantities of analytes (specifically parts per billion) are the major hurdles in the design of chemical sensors from polymer composites (Pawar *et al.*, 2020).

Contamination Control

The expansive industrialization has led to contamination of natural resources with innumerable pollutants. The constant realization of contamination in past few decades has not only moved the scientific, industrial, and governmental organizations to look for less hazardous, renewable, and waste management materials but also for the control of the pollutants for the recovery of natural ecological balance and habitat (Jaspal and Malviya, 2020). Hollow fibrous polymer composite membranes functionalized with iron oxide nanoparticles and graphene oxide nanosheets possess high surface oxygen groups and have the ability to remove the carcinogenic dichlorophenols from water with excellent reusability (Modi and Bellare, 2020). Porosity of the polymer composite membranes for higher surface area and the number of functionalized groups are very important features in the decontamination functionality of the membranes. Reduced graphene oxide functionalization of polyimide to yield nanofibrous membrane shows excellent stability under harsh environment and can remove oil from the polluted water reservoirs (Zhang *et al.*, 2021). Polymer matrix nanofibrous filters made by functionalization with either nitrogen containing or phosphorous containing compounds can treat the uranium contaminated water by electrostatic interactions in a pH-dependent manner (Johns *et al.*, 2020). Other than adsorption of heavy metals, filter membranes can be made to perform catalytic degradation of the organic pollutants such as dyes. Zhang *et al.* designed polymer composite based highly microporous membranes functionalized with polydopamine coated ferroferric oxide nanoparticles to efficiently decontaminate water by simultaneously removing heavy metals and catalytic degradation of the organic wastes. The catalytic degradation is achieved due to the filler polydopamine coating with phenoquinone moieties that induce degradation by promoting electron transfer (Zhang *et al.*, 2020a). Natural polymeric composites of cellulose have been extensively studied for making nanofibrous membranes for water treatment (Tshikovhi *et al.*, 2020). Air decontamination can also be achieved from cellulose based matrix composite functionalized with metal organic framework in chitosan. This highly porous filter paper showed the ability to adsorb the air-borne particulate matter (Nie *et al.*, 2020).

Biomedical Applications

A significant amount of research focus across the globe is to exploit the advancements in the material research for biomedical applications. Multifunctional polymer matrices has paved the way for development of flexible devices that can meet personalized biomedical needs. Not only natural materials but also the synthetic materials have been designed with ample biocompatibility and biodegradability, thus making them suitable for health related applications. The low cost, light weight, huge surface area, and the possibility of multiple modifications and functionalization make polymer composites ideal for application in a range of biological applications (Eslahi *et al.*, 2020).

Antimicrobial Activity and Wound Healing

The growing threat of microbial diseases, the emerging pandemics, development of antimicrobial resistance, and increasing incidences of nosocomial infections due to surface growth of microbes demand design of safe antimicrobial materials for building and devices (Milazzo *et al.*, 2020). Areca fiber reinforced epoxy resin polymer matrix composite functionalized with neem oil and silica nanoparticles show antimicrobial activity against several microbial strains (Samuel *et al.*, 2020). Polymers containing amine groups usually show antimicrobial activity. Chitosan and pullulan composite films display sufficient antimicrobial activity for the films intended for food packaging (Li *et al.*, 2020b). Chitosan and pluronic F127 composite hydrogel when loaded with copper oxide nanoparticles show antibacterial activity against both gram positive and negative bacteria, thus making it a suitable candidate for wound dressing (Jayaramudu *et al.*, 2020). Similarly, chitosan-tigecycline composite films showed significant antibacterial potential against different bacterial strains (Menazea *et al.*, 2020). Interpenetrating hydrogel network loaded with silver nanoparticles of natural gum, acrylamide and acrylic derivative showed both antibacterial and antifungal activities (Sharma *et al.*, 2020). Microbial contamination of surfaces at home or hospital and medical devices such as stents and catheters is an aggressively emerging threat to human health. An antimicrobial polylactic acid film for surface applications was functionalized with polyheamethylene guanidine hydrochloride grafted starch

microparticles. Non-leaching behavior of the films was observed that makes it suitable for surface applications as bacteria will be killed upon contact with the surface (Sharma *et al.*, 2020). An acrylate based cationic polymer film functionalized with titanium oxide nanoparticles for the construction of inner building walls has been shown to possess antimicrobial properties owing to both cationic film and the incorporated filler nanoparticles (Wang *et al.*, 2020a). Improvement in hydrophilicity and swelling behavior of the dressings made with polymer composites show promising control over wound closures. Biopolymer matrix composites based films with good mechanical properties and antibacterial activity have been made for the wound healing applications (Rahmani *et al.*, 2020). Natural polymer composite dressings possessing the functionality for adhesion of cellular components such as red blood cells and platelets are considered effective for closure of wounds associated with hemorrhage (Biranje *et al.*, 2020). Metal nanoparticle incorporated biopolymer composite hydrogel dressings with sufficient antibacterial activity are also potential material candidates for wound healing applications (Gou *et al.*, 2020).

Health Monitoring

One of the current focus of research in healthcare industry is to develop approaches for real-time health monitoring and non-invasive detection of disease biomarkers. Wearable devices containing biosensors are manufactured to monitor the vital signs of patients or athletes. Use of multifunctional polymer composites as biosensors is quite attractive as these materials offer energy storage needed for device operation and stimuli responsiveness to various biological phenomenon (Prajapati and Kandasubramanian, 2019). Polymer matrix composite can be functionalized to measure the body temperature. Temperature changes usually alter the conductivity or capacitance in the functional polymer composites, which can be used for sensing of thermal changes. Dan and Elias demonstrated the thermal sensing performance of reduced graphene oxide functionalized flexible polyhydroxybutyrate matrix composite. Hydrophobic nature of the composite makes it water-resistant thus expanding the thermal monitoring in wet conditions too (Dan and Elias, 2020). Nanofibrous porous composite of Graphene nanosheets with polyamide was developed as a flexible wearable sensor with diverse applications. The designed polymer composite displayed temperature sensing, human motion sensing, and even the physiological electrocardiogram monitoring (Lu *et al.*, 2020). Amperometry based sensing of various biochemical entities in the biological fluids by polymer matrix composite based electrodes has been investigated in recent research studies. A nanohybrid electrode of phototungstic acid-polydiphenylamine-zinc oxide-glassy carbon showed sensitivity for detection of glucose by amperometry (Muthusankar *et al.*, 2020). Similarly, glucose, uric acid, and nitrite in various biological fluids were detected by graphene functionalized polylactic acid electrode fabricated by 3D printing. Glucose was determined in blood, whereas, uric acid and nitrite were detected in saliva and urine samples (Cardoso *et al.*, 2020).

Drug Delivery

Polymer composite matrix can be used as a vehicle for the delivery of drugs inside human body for therapeutic purposes. Biocompatibility and biodegradability are the pre-requisites for drug delivery, whereas, presence of porous structure, structural voids, and functional moieties are advantageous for ample loading capacity of diverse nature of pharmaceutical active ingredients. These materials could also provide protection to drug against chemical or biological degradation, controlled release, and stimuli-responsive organ targeting owing to multiple functionalization. Metal oxide framework functionalized polymer composites have great potential as drug carriers (Chapman *et al.*, 2020; Osterrieth and Fairen-Jimenez, 2020). Gandara-Loe *et al.* (2020) showed that nanocomposite films of metal oxide framework in polymer matrix could be exploited for ocular drug delivery. The versatile fabrication techniques, diverse structural traits, and ease of modification and crosslinking in polymer composites allows facile morphing of these composites into various shapes and sizes. Different shapes and sizes have variable properties and benefits in drug delivery as the interaction of carrier with the biological membranes can be modified on the basis of shape. Vatankhah *et al.* (2020) studied the changes in drug release pattern corresponding to the shape of acrylate composite particles. Polyvinyl alcohol cross-linked chitosan microneedle patches showed substantial controlled release of diclofenac sodium for transdermal application. Degree of cross-linking is crucial in determining the mechanical strength, drug loading, and release performance of designed polymer composite delivery system (Dathathri *et al.*, 2020).

Summary

Multifunctional polymer matrix composites find diverse applications in almost every domain of material science. Use of functionalized fillers has driven the limitless applications and paved ways for new technological advancements. Recently, a noticeable shift in the research of materials is the use of renewable and natural materials to address the ever-increasing issue of environmental safety. The use of natural fibers as polymers, reinforcements or fillers in the polymer composite matrix has advantages in many applications, but it is still too early for natural materials to replace the synthetic one. For example, natural fiber functionalized polymer composites are useful in insulation but cannot be applied for fire retardancy or conductivity applications. Although, synthetic polymer composites also suffer from degradation; natural fibers are more prone to microbial degradation and can easily absorb moisture which can compromise the overall material performance. Conversely, natural polymers are irreplaceable in biomedical applications ranging from health monitoring to drug delivery. Generally, material strength and durability are

compromised by the addition of various fillers. Use of nanosized fillers is revolutionizing the multifunctionalization approach, however, morphology, architecture, size, and dispersion of these fillers need careful attention for each specific functionality. The advanced research in the multifunctional polymer matrix composites has driven flexibility and miniaturization of the devices. Moreover, increased biomedical devices and structures based on these composites are on the horizon.

Introduction

Composite materials consist of two or more diverse components that are chemically or physically networked together. Each of the constituents reveals their distinctive typical properties. The composites comprise of two phases specifically polymer matrix preferably organic phase and reinforcement predominantly inorganic nature. The polymer segments are the continuous phase and fillers are either discontinuous or continuous according to their dimension and length scale. The reinforcement contributes to the asset of the composites and the matrix makes the fillers integral with robust and efficient adhesion. The composites are deliberated as vibrant materials in the contemporary world, owing to their collective properties, viz., light weight, high strength, good stiffness, high thermal stability, low moisture and weather absorption, resist against fire/flame and corrosion, and decent dielectric behavior, which are not conceivable to derive from the single constituents. They are extensively used in the production/fabrication of aerospace structures, packaging of medical and electronic equipments, space vehicle, construction, and etc (Thomas *et al.*, 2012; Cantor *et al.*, 2015; Njuguna, 2016; Mouritz, 2012; Njuguna and Pielichowski, 2003; Toldy *et al.*, 2011; Wang *et al.*, 2011; Mangalgiri, 1999; Devaraju and Alagar, 2018; Quilter, 2001; Ratna and Karger-Kocsis, 2008; Alimuzzaman, 2014; Taj *et al.*, 2007; Liu *et al.*, 2014; Williams *et al.*, 2007; Nurhaniza *et al.*, 2010; Brown, 2014; Toozandehjani *et al.*, 2018).

Polymer matrix composites are one of the most cost inexpensive and advanced composite materials used for extensive range of engineering applications. These composites comprise of either thermosetting or thermoplastic resinous binder reinforced with natural or synthetic materials in the form of fibers, flakes, or particles. They provide an avenue to obtain the improved and optimum properties required for indented applications such as good stiffness and strength, and good corrosion resistance. Polymeric materials have number of benefits over the traditional materials those have been applicable in various aerospace structures (Ratna and Karger-Kocsis, 2008). Owing to their amenable industrial design advantages, including precise strength with a lower weight (weight reduction over the 40%). The other benefits including rapid process for production series, capacity to encounter rigorous dimensional stability, excellent fracture and fatigue resistance, and minor coefficient thermal expansion behaviors when compared to ceramics and metals (Liu *et al.*, 2014). There are numerous potentials for developing composites using diverse combinations of fillers, fibrous additives, and polymer matrices (Alimuzzaman, 2014). These materials play major in advanced composites sector because of their cost competitive, good strength, easy fabrication process, and flexibility in the design (Taj *et al.*, 2007).

Current aerospace sectors are more focused on substituting the secondary structures with fiber based polymer matrix composites, where the fiber used as either glass, Kevlar, carbon, or mixture of these materials (Williams *et al.*, 2007). The necessity for high performance and competence to design material features to encounter definite desires has made the polymer composites a major choice for several aerospace applications. Such materials able to be custom-made to provide good strength combined with reasonably lesser weight, good chemical and corrosion resistance, and to offer longer durability under supreme severe environmental conditions.

Composite Materials in Aerospace Structure

Metals like steel, aluminum, and titanium are utilized to reign extreme in the aerospace applications, accounts about 70% of the aircraft. Yet as hassles for reduction in weight and to improve fuel competence, metals are trailing ground to some of the versatile thermoplastic polymers and composites. The properties of newly developed materials are expected to replace some of the conventional materials in construction of the latest generation of modern aircraft and needs to be assessed their impact on aerospace manufacturing (Mangalgiri, 1999; Toozandehjani *et al.*, 2018).

Until recently, metals are most commonly utilized in the fabrication of aerospace components, conversely, improvements in materials science, specifically in composites field, endorsed the progress of favorable materials for aerospace applications. The huge increase in the costs of aviation turbine fuel (ATF) have ensued in larger request for lesser weight materials in aerospace sectors (Waheedullah Ghori *et al.*, 2018). In the aerospace sector, about 50% of the working cost is exploited for consumption of fuel.

Polymeric composites have key benefits over the traditional metallic materials those are used in diverse aerospace structures. Recent military aircraft have reduced their weight up to 30% with the use of polymer matrix composites. The polymer matrix composites establish ~80% of current launch transportation for satellites, consist of numerous vibrant satellite constituents such as the equipment panels, honey comb assemblies, cylinder sustenance structures, substrates for solar array, antennas, and etc. 30 tons of graphite filled epoxy composites are involved in the space vehicle's (Mouritz, 2012; Waheedullah Ghori *et al.*, 2018). Another significant solicitation of polymers as a bonding agent for linking aerospace constituents. It's probable to acquire good strength, durable links by polymer adhesives. A tinny layer of polymer adhesive is applied to link together with the fiber based

Fig. 1 Usage of polymer matrix composites in aerospace sectors over the years Copyright 2016. Reproduced with permission from In: Rana, S., Figueiro, R. (Eds.), 2016. *Advanced Composite Materials for Aerospace Engineering Processing, Properties and Applications*. Woodhead Publishing Series in Composites Science and Engineering. Elsevier, from Elsevier.

polymer composite and aluminum sheets, that yield the fiber reinforced metal laminate termed as GLARE (Glass laminate aluminum reinforced epoxy), which is utilized to fabricate the fuselage of Airbus 380. The usage of elastomer based materials is generally narrowed to nonstructural aircraft components that need good elasticity and flexibility, including gaskets and seal. Though, polymers with fiber reinforcements or metal sometimes struggle for having more viscosities, higher fabrication temperature and pressure, meager resistance to creep, and etc. Also they look glitches associated to larger weight, aggregation, inadequate stress dissemination, and other aspects (Cantor *et al.*, 2015; Waheedullah Ghorri *et al.*, 2018).

Composites are developed by comprising of two or more constituents, in order to exploit the beneficial features of individual component (Devaraju and Alagar, 2018). Composite materials are most widely used in the aerospace sector in both primary and secondary components, such as engine nacelles, antenna dishes, radomes, vertical and horizontal stabilizers, aircraft wings, center wing boxes, pressure bulk heads, doors of landing gear, engine cowlings, tall cones, floor beams, flap track panels, and etc. The progress of polymer matrix composites usage in viable aircrafts is presented in Fig. 1. The Boeing 777 is a twin-engine jet airliner launched in 2000 with capability of over the 300 travelers, used 11% of polymer composite materials (Table 1). The Boeing 787 Dreamliner, launched in the year 2007, they used over the 50% polymer composites (nearly 3.2 tons of carbon fiber reinforced polymer composites). In recent times, fiber reinforced polymer composites (FRPs), developed with various types of matrices (e.g., metal, ceramic and polymer, etc.), with fiber materials, are attain remarkable consideration in aerospace applications. In today's aerospace sectors, the use of composite materials has enlarged over the 50% (Rana and Figueiro, 2016). For example, the airbus A350 XWB fabricated using carbon-reinforced polymeric composites over 50%, while its colleague, the Boeing 787, also used ~50% polymer matrix composites (Fig. 2) (Brown, 2014). Remarkably, this tendency is not restricted to Airbus and Boeing; other concerns including BAE Systems, Bombardier, GE Aviation, Raytheon, and Lockheed Martin have also tended into use of polymeric matrix composites in their aerospace structures. These improvements in materials are ambitious by numerous factors.

Some of the significant necessities for aerospace materials are specified below.

- (1) High strength
- (2) Light weight
- (3) High damage tolerance
- (4) Good fracture resistance

Advanced Composite Component Materials in Aerospace Structure

Polymeric matrix composites have been several uses in the aerospace sectors. Every so often utilizations do come nearby where the price is secondary anxiety, as usually advanced polymer matrix composites for definite applications are very costly. Such applications including crew gear and cockpit, space optical devices; heat shrinkage pipes, substrates for solar array; high and temperature flare housing, nozzles and shrouds; moldings appliance; durable space mirrors; detectors with high-precision; multifunctional satellite, bus structures; interiors of aircraft; and structural space components (Liu *et al.*, 2014; Lubin, 2013). Advances in polymeric composites will endure to combine with new forthcoming technologies satisfying definite aerospace desires

Table 1 Usage of polymer composites in Boeing aerospace structures

Materials %	Boeing 787 dreamliner	Boeing 777
Launched in	2007	2000
FRPs	50%	11%
Aluminum	20%	70%
Titanium	15%	7%
Steel	10%	11%
Others	5%	1%

Advanced Composite Materials for Aerospace Engineering Processing, Properties and Applications. Woodhead Publishing Series in Composites Science and Engineering. Elsevier, from Elsevier.

(Njuguna and Pielichowski, 2003). Robust engineering technology for polymeric matrix composites will enrich the role of polymers as a facilitating technology, by such features including design optimization, electronics, bio mimetics, reliability and control technology constructing key influences. The outcomes of these expertise will lead to advanced polymer composites with enormous applications including ultra-light aerospace structures or thin films, shape memory polymer for spacecraft, polymers fir electro-active, electro-chromic, and thermo-optical applications (Quilter, 2001; Mouritz *et al.*, 1999; Yan *et al.*, 2008).

The prime emphasis in the progress of an advanced composites have been to discourse their susceptibility to impact destruction (Yadav *et al.*, 2020). The orthotropic behavior of polymer composites consequences in a reasonably low thickness strength which is over and over again alleviated by creating damage lenient designs for structural constituents. Williams *et al.* (2007) examined the influence of the hollow glass fiber (HGF) embedded on the carbon fiber filled epoxy (CFRP) on mechanical behavior, and the healing effectiveness of the laminates after exposed to impact. Samples were confirmed in the damaged, undamaged, and healed conditions with a conventional epoxy healing agent. Rana and Figueiro (Rana and Figueiro, 2016) have categorized the advanced matrix composite in several application based on necessities, structure and fabrication methods as displayed in Table 2.

The aerospace sectors is expected to be the key benefactor of the development of polymer composites as new technology progresses. Frequently, the aerospace application wanted high performance materials with good durability for prolonged life time in sever and volatile climatic circumstances that conventional composite materials struggle to encounter (Waheedullah Ghori *et al.*, 2018).

The Aerospace Structures and Features

The essential necessities of an aerospace assembly and their consequence on the strategy of the structure are depicted in Table 3. Furthermore, the assembly has to full fill the necessities of fuel sealing and deliver admittance for tranquil maintenance of the

Table 2 Advanced composite materials and their properties

Advanced composites	Properties	Materials
Laminated composites	Improved fracture toughness, Enhanced impact properties, Damage tolerance,	E-glass, para aramid fiber, carbon fiber, and other textile based system in various structural design
Sandwich composites	Light weight; Cost effective; Good bending stiffness; Thermal and noise insulation; Damping vibration (Velosa et al., 2012)	Polymer Matrices: Vinyl ester, unsaturated polyester, Epoxy, polyether etherketone (PEEK), polyetherimide (PEI), polycarbonate (PC). Filler reinforcements: Glass fiber (E & S), high modulus carbon, high strength carbon, aramid and Boron fiber.
Braided composites	High shear strength and stiffness; High fracture toughness; High transverse strength and modulus; Fatigue life and damage tolerance and; Notch insensitivity (Rana et al., 2015)	Polymer Matrices: Polyester, Epoxy, PEEK, nylon 6,6, and polypropylene (PP) Filler Reinforcements: Aramid Carbon T300 (Barbero, 2017), Carbon T600 (Carey et al., 2016)
Auxetic composites	Good fracture toughness; Good shear modulus; Good damping resistance; Synclastic curvature; Superior crack growth resistance; High energy absorption ability (Subramani et al., 2014)	Polymer Matrices: Epoxy, polytetrafluoroethylene (PTFE), polyurethane (PU), ultra-high-molecular-weight polyethylene (UHDPE). Reinforcements: Glass and carbon fiber
Ceramic matrix composites	Light weight; High strength; Good fracture toughness; Resistance to catastrophic failure; Good oxidation resistance; Low thermal expansion; Capacity to survive at higher temperature (Hull and Clyne, 1996)	Boron/glass/oxide fibers, SiC HP, aluminosilicate 1720, mullite, Si ₃ N ₄ HP, and glass ceramics nonmachinable 9606,
Metal-matrix composites	High transverse stiffness and strength; High fracture toughness and ductility; High thermal/fire resistance; Good thermal and electrical and conductivities; Good resistance to moisture absorption; Good radiation protection (Clyne and Withers, 1995)	Glass/boron fibers, magnesium, aluminum, and titanium
Nanocomposites	Higher surface area and good interface, Smaller defects, Low volume fraction necessary for the enhancement of properties (Thostenson et al., 2005a)	Phenolic, Epoxy, polyimide (PI), bismaleimide (BMI), PEK, PEKK, elastomers, single/multi-walled carbon nanotube, graphene, etc.

equipments. Traveler carriage wants fire, smoke and toxicity (FST) as per safety criterions to be tailed and these laid distinct demands of crash-worthiness and fire resistant on the constituents and design used. For space craft vehicles the space surroundings including radiation, vacuum, and thermal cycling have to be deliberated for specifically established materials for their resilience in operation. The key parameters involved in the development of scientific-technology related with aerospace applications are influence on the generation and fulfillment of the hassles embossed by aerospace civic has been simplified by computational and modeling tools in the manufacturing ([Mangalgiri, 1999](#)).

Use of Composites in Aerospace Structure

In order to meet the demands for aerospace structures are presented in [Table 3](#), it's essential to devour materials with a typical properties combinations ([Mangalgiri, 1999](#); [Kesarwani, 2017](#)). The use of polymer matrix composite materials has been inspired by such considerations. In precise, the advanced fiber filled polymer composites using aramid/carbon fibers delivers several features as given beneath:

- (1) Light-weight due to high strength and stiffness;
- (2) Corrosion and fatigue-resistance;
- (3) Competence for high-degree of optimization: adapting the directional strength and stiffness;
- (4) Ability to mold for larger shapes in short cycle time;
- (5) Worthy for thinner walled/generously curved construction;
- (6) Competence to withstand the alignment and dimensional stability in space surroundings;
- (7) Probability of lower dielectric loss in radar transparency;
- (8) Possibility of attaining the minimal radar cross section;
- (9) These composite materials also have certain intrinsic weaknesses;
- (10) Laminated construction with fragile interfaces: meager resistance to tensile loads;
- (11) Liability to impact-damage and robust possibility of interior damage going unnoticed;
- (12) Absorption of moisture and subsequent deterioration of elevated temperature performance;
- (13) Diversity of probable manufacturing shortcomings and inconsistency in the material properties.

Even after taking careful considerations of these limitations, the expected benefits are substantial and nearly all aerospace construction uses the sizable portion of polymer based composites.

Table 3 Features of aircraft structure

<i>Requirements</i>	<i>Applicability</i>	<i>Effect</i>
Light weight	All aerospace components	● Semi-monocoque construction 1. Stiffened structures or thinner walled box ● Using lower density materials: 1. Al-alloys 2. Wood 3. Composites ● High stiffness/weight and high strength /weight
Good reliability	All aerospace components	● Severe quality control ● Extensive analysis for consistent data ● Certification: Proof of design
Traveler safety	Traveler vehicles	● Using fire resistant materials ● Extensive analysis: Crash-worthiness ● Extensive fatigue testing
Durability fatigue and corrosion degradation: Vacuum radiation thermal	Aircraft spacecraft	Aluminum alloys don't have a fatigue limit. ● Prevention corrosion schemes ● Concerns of damage and safer life, extension of life ● Extensive analysis for necessary surroundings
Aerodynamic performance	Aircraft reusable spacecraft	● Tinny materials with extraordinary integrity ● Highly complex loading ● Thin bendable wings, control and surfaces 1. Dynamics 2. Distorted shape-aero elasticity ● Complex contoured shapes
Multi-role or functionality	● All aerospace components	1. Manufacturability: N/C machining; molding ● Capable design ● Use: composite materials with varying functional properties
Fly-by-wire	Aircrafts, generally for fighters and also some in traveler a/c	● Structure-control interactions 1. Aero-servo-elasticity ● Widespread use of computers/electronics
Stealth	Precise aerospace applications in military	1. Electromagnetic interference shielding ● Definite surface and shape of aircraft
All-weather operation	Air-craft	1. Stealth coatings. ● Lightning protection, resistance against erosion

Materials for Aerospace Composites

The material structures which have been deliberated beneficial in aerospace industry are based on emphasizing fibers and resin matrices given in [Tables 4](#) and [5](#), correspondingly. Utmost aerospace structures use prepregs as staring materials with autoclave molding as a common construction process. Filament winding is one of standard with similar to shell constituents including rocket motor casings for takeoff missiles and vehicles. For lower speed small aircraft constructed using glass fiber reinforced composites by either room temperature or oven curing. It's collective to utilize composites tooling where production degrees are moderate or small; though, where huge number of constituents are necessary, metallic traditional tooling is desired ([Mangalgiri, 1999](#); [Kesarwani, 2017](#)). Resin injection molding (RTM) also discovers use in distinctive components including radomes.

Table 4 Most commonly used polymeric matrices in aerospace applications

<i>Thermoset</i>				<i>Thermoplastics</i>
<i>Epoxies</i>	<i>Phenolics</i>	<i>Polyester</i>	<i>Polyimides</i>	<i>PPS, PEEK</i>
- Most popular resins used for aerospace. - Composite total usage of about 80% - Reasonably high temperature - Relatively costly	- Inexpensive - Easy to use - Low viscosity - High temperature usage - Very hard to obtain high quality composites	- Inexpensive - Easy to use - More popular at room temperature applications	- Applicable for high temperature applications $\sim 300^{\circ}\text{C}$ - Difficulty in fabrication process - Highly brittle in nature	- Good in damage tolerance - Difficulty in the fabrication process as high temperature $300\text{--}400^{\circ}\text{C}$ is necessary
- Minimal shrinkage (2%–3%); - No volatile release during polymerization (curing). - Can be cured in several methods giving diversities of structures and morphology with widespread range of properties	- High shrinkage - During polymerization release of volatiles - Good inherent thermal oxidation stability - Good resistance against fire and flame retardance - Brittle than epoxies	- More shrinkage (7%–8%) - Better chemical resistance properties - Broad range of properties (lower than epoxies). - Brittle in nature - Lower T_g - Difficulty to make prepregs - Less sensitive to moisture when compared to epoxies		Infinite storage life.
- High storage stability to prepare prepregs - Absorb moisture about 5%–6% result in swelling and degradation of composites at high temperature properties - Led to ultra violet degradation in long duration. - Density: 1.1–1.4 - Tensile strength: 40–85 MPa	- Lower storage stability and difficulty to make prepregs - Absorbs moisture though there is no substantial influence of moisture in operational service range - Density: 1.2–1.4 - Tensile strength: 35–60 MPa	- Density: 1.1–1.4 - Tensile strength: 40–85 MPa - Tensile modulus: 2.7 to 4.1 GPa		- Difficulty to make prepregs - Good resistance against moisture
Tensile modulus: 2.7–5.5 GPa	Tensile modulus: 2.7 to 4.1 GPa	Tensile modulus: 1–3–4.1 GPa		- Density: 1.3–1.4 - Tensile strength: 100 MPa - Tensile modulus: 3.5–4.4 GPa

Reinforcements for Aerospace Materials

Reinforcement (filler) materials incorporated in polymer composites are usually harder, stiffer and stronger, stiffer than the polymer matrix materials. Intrinsically, they performance as the main load resonant component than make up to 60%–70% of the volume of the composites (fiber volume portion). Utmost structural uses trust on continuous, tinny thickness, emphasizing fibers, as these afford a reasonably enormous fiber matrix interface region that consents for superior bonding and load transfer. A series of diverse fiber materials will be utilized to produce thermoset composite fragments, reliant on cost competitive and performance needs. Typical composite material systems used in aerospace applications depicted in [Table 6](#).

Glass fibers (GFs) are one of the widely utilized among all other synthetic fibers as it deliver excellent durability and strength, good thermal stability, impact resistance, chemical resistance, friction resistance, and wear resistant properties. Though, the machining of glass fiber incorporated polymers (GFRPs) is comparatively slow, challenging, and shows compact tool life whereas working on conformist machining systems ([Rajak et al., 2019](#); [Prakash, 2019](#)). Also GFs express the shortcoming of disposal after it uses ([Chalmers, 1991](#)). GFs are relatively inexpensive, have a diameter of 10–20 μm , and are extensively utilized in the automotive and marine applications. Moreover, GFs composites are establish on the secondary components of traveler aircraft, but fairly poor stiffness and strength has prohibited its use on primary components (load-bearing) in the larger aircraft structures, apart from being used as an insulating layer (electrically). One prominent exception is the utilize of GLARE on the top fuselage of the Airbus A380.

Kevlar (Aramid) fibers, of diameter $\sim 12 \mu\text{m}$, afford better stiffness, superior toughness and impact resistance than the glass fibers. These have been utilized for composites on prominent and trailing edge panels, beside with fairings for certain traveler aerospace. Kevlar fiber-reinforced composites (KFRCs) indicate the better impact strength and tensile properties, however, owing

Table 5 Commonly used reinforcing agents in aerospace applications

Fiber		Density (g/cc)	Modulus (GPa)	Strength (GPa)	Application areas
Glass	E-glass	2.55	65 to 75	2.2 to 2.6	Radomes; Small traveler a/c components, Interiors of aircraft, Secondary structure; Rocket motor casings
	S-glass	2.47	85 to 95	4.4 to 4.8	Highly loaded components in small traveler a/c
Aramid	Lower modulus	1.44	80 to 85	2.7 to 2.8	Non-load bearing components, Fairings
	Intermediate Modulus	1.44	120 to 128	2.7 to 2–8	Radomes, Certain structural components, Rocket motor casings
	Higher modulus	1.48	160 to 170	2.3 to 2.4	Highly loaded components
Carbon	Standard modulus (high strength)	1.77 to 1.80	220 to 240	3.0 to 3–5	Broadly used for all types of components in a/c, satellites, missiles, antenna dishes, etc.
	Intermediate Modulus	1.77 to 1.81	270 to 300	5.4 to 5.7	Primary components at higher performance fighters.
	High modulus	1.77 to 1–80	390 to 450	2.8 to 3.0 4.0–4.5	Control surfaces in a/c Space components
	Ultra-high strength	1.80–1.82	290 to 310	7.0 to 7.5	Primary components in high performance fighters aircraft and spacecraft

Table 6 Typical composite material systems used in aerospace applications

Material system	Application area
1. Curing at 175°C high strength carbon reinforced epoxy • Zero-bleed (neat resin content) UD prepregs. • 5HS or 8HS bi-directional fabric prepregs. • Good toughness, good self-life and out-life.	Structural parts of helicopters, and fighter aircrafts. e.g., Doors, wing skins, fin, spars, elevons, rudder, and etc. Stiffeners, frames, and rotor blades Structural parts of transport aircraft and helicopters. e.g., Doors, spars, rudder, fin, elevons, and etc.
1. Curing at 175°C moderated modulus carbon reinforced epoxy/BMI/cyanateester • Zero-bleed (neat resin content) UD prepregs • 5HS or 8HS bi-directional fabric prepreg • Good toughness, good shelf-life and out-life • Lower environmental degradation	Stiffeners and frames Radome For Lightning strike protection, wing-skin, and others Fighters fairings, drop-tanks, and fin-radome Small transport aircraft structural components Wing, fuselage, and other

1. Kevlar (aramid) fiber with low loss polyester/cynate esters 2. Cu-mesh epoxy prepregs 3. Epoxy resins with E-glass fabric	
• Higher temperature curing • Room temperature to moderate temperature curing	

to their anisotropic nature they exhibits lower compression strength when related to their carbon and glass fiber counter parts (Rajak *et al.*, 2019; Unterweger *et al.*, 2013).

Conversely in certain applications, better stiffness is essential, hence, CFs are engaged in its place of GFs. Carbon fiber-reinforced polymer composites (CFRP) have originate beneficial in numeral of applications in automobile, aerospace, sports, and other industries (Yi, 2015; Abramovich, 2017; Chung, 2017). Young's modulus increased by 78% and 113%, respectively, when the weight loading of CFs increased from 10% to 30%. The improvements in the cellular structure resulted in the enhanced Young's modulus (Nobe *et al.*, 2019). Carbon fibers with lower diameter (7–10 μm) reveal greater stiffness and strength, which encouraged their widespread use on larger traveler aircraft including Airbus A350 and Boeing 787. Boron fibers with the diameter of 100–140 μm, provide very high stiffness and strength, but its high cost has largely restricted its uses in aerospace structure. Table 5 associates the precise stiffness and strength of a choice of fiber reinforcements and traditional metals such as aluminum and steel.

The combination of high specific modulus and specific strength CFRPs has resulted in their prime use on the modern traveler aircraft. CFs are generally prepared from the carbonization of spun and exceedingly aligned precursor polymer filaments, using either polyacrylonitrile (PAN), pitch or rayon. Synthetic PAN is generally prepared using acrylonitrile (CH_2CHCN) by free radical polymerization. It's the extensively used precursor material, at around 90% of the precursor market, and it results in the highest quality fibers.

Graphene fibers are a new type of high-performance carbonaceous fibers that possesses good tensile strength and higher electrical conductivity when compared to those of carbon fibers. Numerous superior properties of graphene fibers display their potentiality in a diversity of applications, including conductive cables and wires with lower weight, knittable super-capacitors, actuators, micro-motors, solar cell textiles, etc. (Xu and Gao, 2015; Sreenivasulu *et al.*, 2018). The molecular dynamics simulation of graphene reinforced polymer nanocomposites revealed enhances in shear modulus, Young's modulus, and hardness by 27.6%, 150%, and 35%, respectively. Further, a reduction in the coefficient of friction and abrasion rate by 35% and 48% respectively was achieved (Li *et al.*, 2017).

In certain applications, apart from less weight, higher performances are one of major prominence in aerospace structures, e.g., aircraft interiors, equipment enclosures, cockpit, coatings, heat shrinkage tubing, crew gear, space durable mirrors, shrouds, housings, nozzles and substrates for solar array. Composite materials afford good chemical resistance and fire retardancy apart from the benefit of low working cost owing to its lightweight (Peng, 2011).

There are three main shortcomings limits its feasibility of composite materials in most of the aerospace structural components.

- (1) High electrical resistance can lead to restrict EMI shielding, antennas, circuits and lightning strike protection applications (Rathod *et al.*, 2017).
- (2) Poor thermal conductivity of the composite materials rises the load on deicing systems founded on electrical heaters.
- (3) Generally composite materials are poor resistant to impact and be distressed from absorption of moisture, degradation against environment and aging by time (Mahieux, 2006; Martin, 2008).

Depending upon the polymer matrices and reinforcement used, several solutions have been accessible by nano-composites to overwhelm these shortcomings. Some of the polymer nano-composites and their air-craft applications are discussed in the later section.

Merits and Demerits of Polymer Composites in Aerospace Applications

1. Merits of composites:

- Weight reduced 20%–40% with definite strength properties.
- Owing to the light weight fuel consumption is lower.
- Probable for prompt production development cycles.
- Lower coefficient thermal expansion behavior.
- Capability to meet rigorous dimensional stability.
- Better fracture and fatigue resistance over the ceramics and metals.
- Better impact resistance and good damage tolerance increases accident survivability.
- Mechanical properties be able to alter by "lay-up" techniques, with narrowing thicknesses of reinforcing cloth and cloth orientation.
- Advanced polymer composite materials are good corrosion resistance properties than metals.

2. Demerits of composites:

- Higher recurring and non-recurring costs.
- Higher material costs.
- High fabrication costs.
- Non-visible impact damage.
- Repairs are diverse than those to metal structures.

Thermoplastic Composites in Aerospace Applications

Thermoplastics are an alternative to thermoset polymers used in the development of composites and hold promise for increasing production rates. Unlike composites prepared with thermoset polymers, thermoplastic composites do not require a curing step after consolidation, in which the composite is formed by applying heat and pressure to multiple prepregs layers to form a solid laminate. Thermoplastic composites simply essential to be heated up past the melting point of the thermoplastic matrix, consolidated and cooled, unlike thermoset composites which require a curing time for polymer cross-links to form network molecular structure (Barile *et al.*, 2020; Marsh, 2007, 2013).

Table 7 Most commonly used thermoplastic polymers in aerospace applications

Chemical name	T_g ($^{\circ}\text{C}$)	T_f ($^{\circ}\text{C}$)	Crystallinity	Main characteristics	Cost ($\text{€}/\text{Kg}$)	Sector
Poly ether imide (PEI)	215	–	Amorphous	Outstanding FST properties; Restricted chemical resistance	15–20	Aerospace Interiors
Poly ether sulfide (PES)	220	–	Amorphous	Toughness; low density	1–3	LFT; flexible Pipes
Poly ether ether Ketone (PEEK)	140–145	334–343	Semi-crystalline	Superior chemical resistance; High thermal performance	60–80	Aerospace; Medical
Poly phenyl sulfide (PPS)	85–90	275–290	Semi-crystalline	Excellent chemical resistance	15–25	Aerospace; Industrial

Thermoplastic composites for aerospace applications use high-performance thermoplastic resins, including polyetheretherketone (PEEK), polyetherketoneketone (PEKK), polyaryletherketone (PAEK), polyetherimide (PEI) and polyphenylene sulfide (PPS) (Red, 2014; Gardiner, 2010; Macdonald, 2018; Olson; Favaloro, 2017). Aerospace thermoplastic composites typically have percentages of carbon fiber around 50%–60% by volume. The ratio of carbon fiber to thermoplastic resin is tailored to attain the preferred mechanical properties and compatibility with the manufacturing process. A higher ratio of fiber to resin is desirable for maximizing mechanical performance, but may be more suitable for manufacturing processes with longer cycle times and higher pressures. Lower ratios of fiber to resin may accommodate faster process cycles and lower pressures.

Polyaryletherketones (PAEKs) are prepared by linking the ether groups with ketone groups and the mode these functional are organized in the ultimate molecule categorizes the several parts of the family. The proportion of ketone group decides the melting temperature. They are semi-crystalline thermoplastic polymers with a wide-ranging of melting temperature, high stiffness, strength, and higher resistance to hydrolysis, which mark them appropriate for several applications challenging extreme circumstances.

Polyetheretherketone (PEEK), are one of the most substantial thermoplastic polymers used for fabrication of aerospace structural components. These PEEK structures are designed specifically from the replication of 2 ether groups and 1 ketone group. The existence of aromatic rings and ketone group deliberate a definite degree of rigidity to the PEEK structure, diminished though by the inclusion of ether linkages. For this intention, PEEK devours the low melting temperature than that of other similar compounds including PEK or PEKK. Table 7 show the major properties and cost of the thermoplastic polymers most widely used in aerospace structural applications. In addition, it's worthy to discuss that the PEKK as semi-crystalline thermoplastic polymers which is recently evolving for a broader range of applications, including the probable construction of primary aerospace structures through out-of-autoclave fabrication processes. Diverse properties of PEKK and PEEK, are owing to their different molecular structures, which denote that PEKK reveals good compression strength of up to 80% and broader processing parameters than that of PEEK. Further, the melting temperature of PEKK possesses in the range between 280 $^{\circ}\text{C}$ and 390 $^{\circ}\text{C}$ and T_g of 150–165 $^{\circ}\text{C}$. The specific molecular structure of PEKK donates to greater fusion properties when compared with those of other polymers and metal, which prompted fascinating applications. PEKK can be placed at zenith of the PAEK class, which provide the distinctive chemical, physical and mechanical properties (Barile *et al.*, 2020).

Thermosetting Composites

Thermosetting polymer composites are extensively used subdivision of the PMC that undergo an irreversible polymerization process that facilitates molecular cross-linking during fabrication. The physical and mechanical properties of thermosetting polymer matrices are given in Table 8. Before dealing that the thermosetting polymers that mark up the matrix composite are generally combined of individual macromolecules that stream reasonably free from a liquid or soft tacky solid under the heating. Then these are cured at higher temperature and pressure with or without catalysts to fabricate the cross-linked polymer composites. In order to design a suitable composites structure for aerospace applications, it's significant to realize the properties of both the resin polymers and fiber reinforcements that subsidize to the complete composite performance (Falzon and Pierce, 2020; Hamerton and Kratz, 2018; Black, 2004; McConnell, 2009).

In aerospace sectors, numerous advanced thermosetting resins are most apparently utilized, amongst which epoxy resins are one of most predominant and well-studied. Epoxy resins afford a wider range of gorgeous properties, such as high definite stiffness and strength, and excellent fatigue and corrosion resistance (Toldy *et al.*, 2011; Alagar *et al.*, 1999; Bondzic *et al.*, 2006; Brocks *et al.*, 2013; Vengatesan *et al.*, 2011; Devaraju *et al.*, 2013a; Selvi *et al.*, 2019; Ashok Kumar *et al.*, 2002). By the adding the additives such as thermoplastic polymers to further enhance the properties including impact strength, toughness and moisture resistance. The appropriate epoxy formulations can be used to increase the service temperatures as high as 120 $^{\circ}\text{C}$, which is essential to meets the desires of sub-sonic aerospace structures. Though, thermal degradation of the epoxy resin turn into tricky for high temperature areas such as the nacelle and engine structures, or the aerodynamic sides of supersonic aircraft, where specific resins must be used. Usually, epoxy resins are high cost than the vinyl ester and polyester resins, predominantly when enriched with extraordinary performance additives. For interior of the cabin, where mechanical performance is less significant though the resistance to fire and lower emission of smoke are crucial, phenolic resins are usually employed. These are moderately low cost when compared with

Table 8 Physical and mechanical properties of thermosetting polymer matrices

Properties	Epoxy	Phenolic	BMI	Cyanate ester	Phenolic triazine resin	PBZ's
Density (g/cm ³)	1.20–1.25	1.24–1.32	1.20–1.30	1.10–1.35	1.25	1.19
Maximum use temperature (°C)	180	200	~200	150–200	300	130–280
Tensile strength (MPa)	90–120	24–25	50–90	70–130	4.2	100–125
Tensile modulus (GPa)	3.1–3.8	3–5	3.5–4.5	3.1–3.4	4.1	3.8–4.5
Elongation (%)	3.0–4.3	0.30	3.0	2–4	2.0	2.30–2.90
Dielectric constant (1 MHz)	3.8–4.5	4.1	3.4–3.7	2.7–3.0	3.1	3.0–3.5
Curing temperature (°C)	RT–180	150–190	220–300	180–250	177–316	160–220
Cure shrinkage (%)	>3	~0	~0	~3	~3	~0
TGA onset (°C)	260–340	300–360	360–400	400–420	410–450	380–400
T _g (°C)	150–220	170	230–380	250–270	300–400	170–340
G _{IC} (J/m ²)	54–230	760	160–250	786	120	70–300
K _{IC} (MPa√m)	0.6	1.01	0.85	0.3–1.45	0.2–03	0.6–1.1

similar kind of fire-resistant techniques, and deliver better thermal stability, high strength, good dimensional stability and good resistance to creep at the low cost and reduced mechanical properties when compared to that of epoxy resins.

Cyanate ester are another specialized thermosetting material that are usually used in composites for aerospace antennae/radomes owing to its greater electrical properties. They afford greater toughness, strength, minimal moisture absorption, good thermal stability and high fire retardancy properties however these resins are comparatively costly (Falzon and Pierce, 2020; Hamerton and Kratz, 2018; Black, 2004; Fang and Shimp, 1995; Hamerton and Hay, 1998; Saxena and Maiti, 2020; Lockney, 2008; Hay *et al.*, 1989; Simpson *et al.*, 1991; Chen *et al.*, 1997; Harvey *et al.*, 2017; Iredale *et al.*, 2017). Therefore, their usage is fairly restricted. The effort to the superior resin properties, including good damage tolerance and high thermal stability, has directed to significant interest in other interesting polyimide (PI), bismaleimide (BMI) and benzoxazine (BZ) resins that can be mainly more costly. PI polymeric resins needed high temperature and pressure for processing, along with a long curing cycle, and display superior processing difficulties including release of volatile gas and moisture during polymerization. Conversely, these polymeric resins resulted in a greater thermal properties compared to epoxy resins; which joined with better chemical resistant and good adhesion properties marks them ultimate for low weight fabrication, missile and jet engine components. The meticulously BMI resins reveal comparably high thermal stability and are utilized on high enactment aircraft including the F35 Lightning II Joint Strike Fighter.

Benzoxazines are widely utilized for aerospace applications wherever hot/wet performance or resistance to fire is crucial constraint, although these resins persist comparatively new one when compared to that of other resins and were formerly proposed for interiors of aerospace structures. Also BZs afford abundant potential for hybridization with epoxies, phenolics or BMI owing to their molecular structure with reactivity. These matrices can accomplish better fire resistance and mechanical properties due to the higher percentages of aromatic segments and higher molecular than those of phenolics/epoxies and less expensive than BMI (Kiskan, 2018; Ghosh *et al.*, 2007; Ishida and Froimowicz, 2017; Ishida and Agag, 2017; Santhosh Kumar and Reghunadhan Nair, 2010; Devaraju *et al.*, 2019). Consideration for the expenditures in associated with handling, storage, processing, layup, finishing and repairing, it has been advised that BZs might be even inexpensive with epoxy resins. This may owing to its room temperature stability, which contradicts the necessity for ice-covered storage and thawing.

Epoxy Composites for Aerospace Applications

Epoxy resins are attracted as one of the significant thermoset resins widely used as matrices in almost all of the advanced composites system due to their easy changing of the physical state from a lower viscosity to a high melting solid, a extensive range of materials with distinctive properties including good adhesion/impregnation to fiber, ensuing in admirable chemical, and mechanical properties, electrical resistance and minimal shrinkage during curing. Due to diverse physico-chemical, and mechanical stuffs make them appropriate for a widespread range of engineering and other sectors including paints and coating, construction and flooring, food packaging, automotive and public transports, water pipe works, energy, electronics and ICT, sports and aerospace.

The most usual and most broadly deliberated epoxy is the diglycidyl ether of bisphenol-A and its accessible in a different variety of molecular weights ($n = 0.2, 400 \text{ g/mol}$ to $n > 12, 4200 \text{ g/mol}$). Tri-functional epoxy for example TGAP (Scheme 1) result in high cross-linking density and are a mutual constituent in recent epoxy formulations, being co-cured with diglycidyl ether of bisphenol-A. The usage of epoxidized novolacs are able to achieve the high cross linking densities result in higher T_gs (Scheme 1). The presence of higher amount of aromaticity prominent to excellent thermal properties and good abrasive resistance. The typical 1st generation aerospace epoxy materials was prepared using tetra functional epoxy as tetraglycidyl-4,4'-diaminodiphenylmethane (TGDDM) and 4,4'-diaminodiphenyl sulfone (DDS) as hardener (curative) resulted in highly thermally stable cross-linked network structures. Though relatively these epoxy network possesses brittle in nature. This may be overcome with the

Scheme 1 Typical epoxy resins used in aerospace applications.

use of suitable elastomers (e.g., butadiene acrylonitrile elastomer with terminated carboxyl group) and certain engineering thermoplastics including polyethersulfones oligomer with terminal amine groups.

The first usage of epoxy composites in the aircraft components in the year 1970s. They used boron filled epoxy composites for the fabrication of empennages skins of US fighter airplanes namely F14/F15. At the beginning, epoxy composite materials were utilized only in secondary components of aircraft parts, then quickly engineers recognized epoxy composites are more appropriate to making the primary structures of aircraft including fuselages and wings, to enhance the overall properties of the aircraft. Actually, F15 aircraft they used ~2 wt% of composite materials, in F18 it increased to 19 wt% and in F22 further increased to 24 wt%. Its not taking longer time for viable aircrafts to trail the routes of trailblazing defense applications. European Airbus Corporation seen their prospective early in the 1980s, in progress to work composite materials in certain of its viable aircrafts including Airbus A300 and A310.

Use of epoxy in the aircraft.

- (1) Reduced weight.
- (2) Good fuel economy.
- (3) Heavy duty intermediates.
- (4) Minimal CO₂ emission.
- (5) Improved cabin climate.
- (6) Better airplane's carbon footprint.

Alagar research group (Alagar *et al.*, 1999) have developed two different kinds of siliconized epoxy hybrid matrix using DGEBA epoxy and hydroxyl terminated polydimethylsiloxane (PDMS). The weight percentage PDMS in epoxy matrix was optimized based on physico-chemical, thermal, mechanical, and electrical properties. The siliconized epoxy matrices cured with different hardeners including polyamidoamine, aromatic amine, aliphatic amine, and 3-aminopropyltriethoxysilane (APTMS). Later, the optimized siliconized epoxy matrix are reinforced with various fillers and additives such as SiO₂, BaSO₄, and TiO₂, dioctylphthalate (plasticizer), tris (2-chloropropyl) phosphate (flame retardant additive) and Kevlar-49 and E-glass fiber (reinforcement) and studied their thermal, mechanical and electrical properties. Inclusion of siloxane fragments in to epoxy systems show improved electrical properties with minimal reduction of mechanical stability. Additives and reinforcements enhanced the electrical and mechanical properties to substantial extent. From the results, disclose that the fiber (Kevlar 49 and E-glass) filled siliconized epoxy composites can be utilized in aerospace and other engineering applications.

Toldy *et al.* (2011) research group reported the carbon fiber-reinforced composites from phosphorus-containing reactive amine used as curative, cross-linking agent and flame retardant for both aliphatic and aromatic epoxy systems to achieve the strong necessities on mechanical properties of the aerospace applications. The flame resistance properties was analyzed with suitable tests and cone calorimeter. In addition to the flame resistance, the tensile strength and impact strength and inter-laminar shear strength were checked and reported. The fiber introduced multilayer composites reveal the better mechanical and flame retardancy properties.

Meenakshi and Ananda kumar research group (Shree Meenakshi *et al.*, 2011) reported the development of 10-dihydro-9-oxa-10-phosphaphenanthrene-10-oxide (DOPO) based phosphorus tetraglycidyl epoxy nanocomposites for aerospace and other high performance applications. 4,4'-Methylenedianiline (DDM) and bis(3-aminophenyl)phenylphosphineoxide (BAPPO) used as hardener(curing agents) for epoxy polymerization. Nanoclay and monofunctional amine terminated polyhedral oligomeric silsesquioxane (POSS) used as nano-filler for epoxy resin. Then they studied the thermal, mechanical, electrical, flame retardant, and moisture absorption properties of the epoxy nano-composites and discussed. From the data obtained, is concluded that the DOPO based epoxy nanocomposites with enhanced mechanical, thermal properties, flame resistant, dielectric properties can be useful in many fields including electronics, automotive, and advanced aerospace applications with improved performance and enhanced longevity.

Scheme 2 Polymerizable monomeric reactants (PMR) concept shown for selected examples (PMR-15, PMR-II-30, and LARC 160).

Development of conductive adhesives through appropriate structural competence is essential to accomplish both electrical and structural adhesive relationship of aerospace structures. In recent past, nano reinforcements including carbon nanotubes (CNTs) are focused in the development of conductive adhesives. The introduction of CNTs in to polymer matrices significantly enhances the mechanical stability and electrical conductivity of the resulting (i.e., epoxy resin) polymers. In this connection, Benoit Simard (Jakubinek *et al.*, 2015) research group reported the structural and conductive adhesive based on single-walled carbon nano-tubes (SWCNTs) introduced in to aerospace-grade epoxy system at low level filling of up to 1 wt% to enrich the electrical conductivity without affecting the structural bonding ability. At lower loading of SWCNTs in to epoxy maintained or improved the tensile strength, though in case of high loading of SWCNT decreased the strength. The lap-shear and peel tests were performed to assess the structural bonding ability in the joints of composites-to-composites, judiciously retained for adhesives comprising 0.5 and 1 wt% SWCNTs. In case of the 0.5 wt% SWCNT loaded epoxy indicated that there is no change in adhesive, peel and lap-shear strength and it retains the properties. While 1 wt% SWCNT introduced epoxy showed peel strength increased to 30% but the lap-shear strength was decreased to 10%–15%. For 1 wt% SWCNT–adhesives, conductivity values was achieved to 10^{-1} – 10^{-3} S m⁻¹. The developed epoxy adhesive with good conductivity will be suitable for aerospace structures.

Polyimides in Aerospace Applications

Polyimides are one of the most important high performance thermosetting polymers owing to their outstanding thermal and thermo-oxidative stability (Saxena and Maiti, 2020; Lockney, 2008; Hay *et al.*, 1989; Simpson *et al.*, 1991; Chen *et al.*, 1997; Harvey *et al.*, 2017; Iredale *et al.*, 2017; Kiskan, 2018; Critchley *et al.*, 1983; Mittal, 1984; Devaraju *et al.*, 2018). Generally, the aromatic PIs containing a heterocyclic imide unit in the polymer backbone can be used in manufacturing current automotive/aerospace sectors and microelectronic device applications. It is the curiosity of both industrial and academic research to expose the most favorable approaches for making PI materials custom-made to these budding manufacturing comforts. The reasonably the rigid assembly of PIs provide higher T_g of over the 280°C, good mechanical stability. The linearity and rigidity of the cyclic backbone permits for molecular arrangement. This occurrence consequences in reduced CTE than other thermoplastic polymers with flexible and coiled chains. Furthermore, the morphology of lengthy and linear ordered chains affords good solvent resistance properties to the PIs. The evolution of current technology has postured a frequently increasing requirement for materials that can fit under severe conditions, including higher temperatures. These PIs are notorious for their elevated temperature performance in the range of 400°C and 500°C along with good resistance to almost of the chemicals. They are utilized to substitute the traditional materials of metals, and even iron in several engineering applications. Due to its outstanding thermal and mechanical properties make them useful in many applications including flat panel display, high temperature fuel cells, and aerospace applications including military uses.

Polyimides (PI) are used in the form of films, plastics, laminates, coating materials, and high thermal adhesives. PI's be present in two forms including both thermoplastic and thermosetting form. Depends upon the components of their main chain, PI can be categorized as aliphatic, semi-aromatics, aromatics, thermosets and thermoplastics. Traditional linear PI's possesses a higher melt viscosity that restricts their processing capability and final-use of the applications. To overcome this issue, by introducing reactive end-capping agents and reducing the molecular weight to produce thermosetting polyimide with improved processability.

Thermosetting PI's especially, polymerizable monomeric reactants (PMR) were initially developed in the year 1970s at US Air Force at NASA Langley research center for military applications in order to meet the working temperature of 242–374°C to utilize in aircraft engine nozzle, nacelles, gear cases (helicopter), and missile. Generally, PMR was synthesized using aromatic diamine, a dialkyl ester of tetra-carboxylic acid and a mono-functional nadic ester as end-capping agent and the structure is presented in **Scheme 2**. PMR is named according to the use of aromatic di-anhydride ester and aromatic diamine and are demonstrated by PMR-15 (T_g – 370°C), PMR-II-50 (T_g – 340°C), and LARC RP-46 (T_g – 393°C). PMR chains consist of imide systems terminated with nadic anhydride groups (Hamerton and Kratz, 2018; Black, 2004; McConnell, 2009). However, PMR-15 and comparable variants exhibits better mechanical and thermal properties, they comprise the unsafe nature of methylenedianiline (MDA) as carcinogen, making a potential health and safety concern. In this regard, NASA research group initiated to develop new varieties, using less hazardous monomers. The development of LARC RP-46 in 1991 to replace the PMR-15 with very similar approach using 3,4'-oxydianiline instead of MDA (Hay *et al.*, 1989; Simpson *et al.*, 1991). In order to attain the desirable thermo-mechanical performance, high post-cure temperatures need be employed (for e.g., in PMR-15; curing 24 h at 371°C results in a T_g values of 370°C, while a curing performed 50 h at 1 bar pressure resulted in T_g value of 388°C). The application of autoclave cure restricts the release of pentadiene from the norbornene segments via a retro-Diels-Alder reaction, consequently permitting it to react with maleimide to make the cross-linked networks (Hay *et al.*, 1989). Though, this challenging processing technique confines the broader adoption directed to more difference in the feature of the resulting composites thus produced (mostly for thick components); furthermore, PMR-15 is found to be vulnerable to micro-cracking and thermal spiking (Simpson *et al.*, 1991).

Harvey *et al.* (2017) research group developed PMR-PCy PI oligomer using less hazards 4,4'-methylenbis-(5-isopropyl-2-methylaniline) bisaniline prepared from the *p*-cymene as renewable materials. The developed PMR-PCy possesses high T_g of 323°C, better thermo-oxidative stability, and lower water absorption (3%). As per the quantitative structure activity relationship (QSAR) anticipated less hazards nature of CDA is confirmed with in-vitro analysis for muta-genicity, aquatic toxicity and acute toxicity. CDA is observed to be non-mutagenic (Ames) test, had expected 725 mg/kg in rats for LD_{50} , 299.3 mg/L for EC_{50} . These consequences propose that CDA is no to less hazards to humans. The mixture of extraordinary material properties combined with the less hazards of CDA propose that PMR-PCy might be a feasible non-hazards substitutes for PMR-15 in a diversity of aerospace components.

Advanced composite materials research (YLA U.S.A.) prepares 90% of Unitech's prepregging, for their clients for aerospace applications. Several patented materials are existence manufactured using RP-46, together with a high thermal bearing for a viable aerospace engine and radomes application. Due to its tremendous electrical properties which is the main motivation to chosen by the radomes producer. Phenylethynyl-terminated imides (PETIs) has been another invention of the Langley NASA research group developed high speed public transport, the materials provide low melt viscosity by the inclusion of an unsymmetrical dianhydride and high value of T_g of 330°C (PETI-330) and 365°C (PETI-365) depends on the monomer selected. To make great efforts to achieve for good thermal stability, the non appearance of free diamines marks these materials more gorgeous to several users when compared to that of PMRs, however this is compensated by the challenging fabrication desires such as infusion temperature 280°C and cure temperature 371°C and more costly (Hamerton and Kratz, 2018; Black, 2004).

Super imide polyimide is a PMR- type polyimide successfully developed in the early 1990s by Goodrich Corp.'s the chemistry based on high levels of aromaticity with adaptable performance features. It was commercialized in 2000, since the time, over one million fabricated components were used in aerospace applications including aircraft brake and jet engine (Hamerton and Kratz, 2018; Black, 2004). Numerous varieties of Super imide are currently available. Super imide resin based constituents afford high ranks of thermo-oxidative stability, working temperatures over the 343°C. For usages where the thermal spikes are met, Goodrich retains that super imide materials may readily survive tedious thermal spike temperatures of over the 537°C.

Maverick Corp commercialized the 2nd generation non-MDA based PI's. Maverick also trades the conventional, military-qualified MDA-containing PMR II-50, MVK-19, and AFR700 PIs. The Maverick resin has been developed in connection with Glenn research center NASA, with cheap price. The components parts (complex shape) are fabricated using resin transfer molding (RTM), similar to aerospace engine cooling pipes with operative temperatures of 260°C, be able to prepare with interwoven reinforcement. Cured portions reveal higher T_g about 335°C and good thermo-oxidative stability in aerospace engine atmospheres (Black, 2004).

Kapton is an aromatic PI prepared using pyromellitic dianhydride (PMDA) and 4,4'-diaminodiphenylether (DDE) to prepare the polyamic acid (PAA) solution, which is later thermal or chemical imidized to get the PI films. For the last 15 years, Kapton PI films has been implemented as the key wire and insulation cable for over the seventy commercial and military airplane, missile and space vehicle uses. This extensive acceptance is owing to their light weight, minimal smoke harmfulness, high electrical properties, good mechanical toughness, resistance to chemicals, and the capacity to survive severe of temperature.

Bismaleimides in Aerospace Applications

Bismaleimides (BMIs) has been the type of PI synthesized from the diamine and maleic anhydride deal lower enactment than PETIs/PMRs. Though the BMIs bridged between epoxies and the PMR polyimides in comparison of cost and properties and are

Scheme 3 Preparation of polyaspartimides (addition polyimides) from Michael addition reaction of BMIs with diamines.

doubtfully the most imperative family of addition PIs assumed more extensive usage in Lockheed Martin's F-22 Raptor and the F-35 Lightning II Joint Strike Fighter but also in civil aerospace sectors. Brittleness is one of key issue of conventional BMIs used in airframes. This issue may be over-whelm by blending with appropriate thermoplastic or elastomeric components. Another method, lowering the cross-link density of BMIs via the development of oligomers to improve the toughness (Kwiatkowski *et al.*, 1975) or the introduction of diamine through Michael addition to produce aspartimides (Scheme 3) (Barton *et al.*, 1994). Though, the introduction of diallylbisphenol-A based co-reactive components (Matrimid 5292 ($T_g = 295\text{--}310^\circ\text{C}$ and $GIC = 195\text{--}217\text{ J/m}^2$)) (Reghunadhan Nair, 2004) or alkenylphenylethers (Compimide TM123, $T_g = 250\text{--}260^\circ\text{C}$ and $GIC = 400\text{--}500\text{ J/m}^2$) (Stenzenberger, 1993) were used to produce second-generation BMIs. Modified BMIs indicate significantly improved toughness that meets equal or higher than that of PIs.

Phthalonitriles in Aerospace Applications

Phthalonitriles are aromatic compounds that produce highly cross-linked network structure which result in excellent thermal stability (Hu *et al.*, 2015). A model scheme for the preparation of phthalonitriles and a highly cross-linked triazine final product are presented in Scheme 4. The length of the oligomeric segments (calculated by O-Ar-O) influences the processing skill, agreeing melting temperatures of $40\text{--}50^\circ\text{C}$ to be attained with an extensive fabrication window of up to 200°C . However once cured at 250°C and post cured at 480°C , the polymer networks indicate no softening $\sim 500^\circ\text{C}$. Moreover, the post cured polymeric material possesses the tremendous short-term contact up to 8 min at the temperature range between 371°C and 538°C . Over the 550°C , phthalonitriles resin carbonized to produce high residue of $>80\%$ at 1000°C . Commercial phthalonitriles (MVK-3), developed by Keller *et al.* in the Naval Research Laboratories (NRL). These are suitable RTM or vacuum-assisted RTM (VRTM) and prepregs (Hamerton and Kratz, 2018).

Carbon fiber and fiber glass reinforced phthalonitrile matrix composites reveal high values of $T_g \sim 450^\circ\text{C}$ and good thermo-oxidative stability over the 371°C as mentioned in the Keller report. The strength especially in fracture toughness and tensile properties of neat phthalonitrile resin showed better or equivalent to the PIs. Phthalonitrile composites showed very high residue and minimal smoke and hazards-gas generation during burning and are only polymer composites to meet the fire resistance properties as per flammability standards of U.S. Navy's (MIL-STD-2031) (Black, 2004).

Eikos Inc. (U.S.A.) has been traded the phthalonitrile resins, which are prepared by in collaboration with JFC Technologies Inc. (U.S.A.). GKN Westland Aerospace Inc. has used woven carbon fabric reinforced phthalonitrile by resin transfer mold for an aircraft engine part to replace the titanium metal. From data obtained from simulated working circumstances for rotor-craft, humidity and temperature, which exhibited that phthalonitrile composites engaged the mechanical properties over the range of -54°C to 343°C and it possesses better performance than that of other resins tested.

Cyanate Esters in Aerospace Applications

Among all cyanate ester (CE) resins are most significant thermosetting polymers developed in the recent past. Cyanate esters have stimulated a wide range of attention because their good performance behavior suitable for number of uses in connection of their

Scheme 4 Schematic representation for polymerization of phthalonitriles.

gorgeous physical, high thermal stability, excellent mechanical and electronic properties. These resins are high temperature thermosets and are widely used in structural aerospace, electronics and microwave-transparent composites. A large variability of CE resins with diverse backbone structures with wide range of properties are available. Usually the CE resins is prepared using phenol and cyanogen halide in presence of a mild base (Hamerton, 2004; Bajpai *et al.*, 2020; Fang and Shimp, 1995).

Cyanate esters are remarkable and valuable material towards industrial uses and are polymerized via a cyclotrimerization reaction (Scheme 5) to form a high degree of proficiency, using amine or metallic catalyst be able to reportedly attain the conversions over the 98%. The wide range of properties of CE sorts them versatile and suitable material for utilized in a diversity of applications from aerospace to microelectronics. Aerospace sectors including high thermally stable adhesives and structural components. Their transparency to radar energy and microwave keeps them suitable for conical radome nose cones. Micro-crack and impact resistance characteristics of CE find beneficial for communication satellites, aircrafts components and engine pistons. CE resins and composites are mainly utilized in high-significance applications where enactment at whatever prices is critical. CE resins are widely utilized in high speed printed circuit boards (PCBs), high performance EMI wave entered structural constituents and aerospace components owing to it excellent properties, including low dielectric constant and low dielectric losses, better adhesion strength and mechanical strength, resistance to wet/hot circumstances and processing (Devaraju *et al.*, 2013b; Jothibasu *et al.*, 2012; Zhou *et al.*, 2020; Li *et al.*, 2019). Though, they main shortcoming of high brittle behavior triggered by three dimensional cross-linked networks in the polymerized CE resins. Hence, toughness behavior of cyanate esters needs improvement of impact behavior using suitable polymer modifiers for improved longevity and high performance applications. CEs are superior in thermo-mechanical and hot/wet performance over the epoxy resins, also it directly matches with BMIs in some extents in terms of performance and cast. The processing of CEs quite easy and can be toughened by co-reacting with epoxy resins. Primaset PT resins (phenolic triazines/cyanated novolacs) such as PT30 (Lonza AG) possess similar fire, smoke and toxicity (FST) properties to traditional phenolics but yield high T_g of 400°C (Hamerton and Kratz, 2018). The electrical properties indicated that dielectric constant value of $K \sim 3$ and dielectric loss (dissipation factor) of 0.002–0.003 mark them of specific attention for example, Cycom 5245C and Cycom 5575–2 are engaged in radome structures and in the wing of Rafale fighter jet.

Phenolic Resins in Aerospace Applications

Phenolic resins are one of oldest and traditional synthetic resins and stand up from the innovative effort of Baekeland (Bakeland, 1907). They prepared phenolic resins through poly condensation reactions using phenol and formaldehyde in acidic environment (excess in phenol) to obtain novolacs or under basic environment (excess in aldehyde) to yield resoles (Scheme 6). Both novolacs and resoles are almost the similar type of high aromatic structure with short methylene connections, when combusted, the subsequent thermosets exhibit outstanding thermal stability, flame and heat resistance, minimal-smoke, and minimal toxicity of emission [fire/smoke/toxicity, (FST)] properties than those of other commercial thermosets. These thermal properties are related to resistance to chemical, good mechanical stability, and good retention of properties at high temperatures that mark them gorgeous, while T_g values of polymerized phenolics are comparatively lower (160°C) and by succeeding post cure may exceed 300°C. Over the 300°C some of the degradation of cured phenolic resins is perceived owing to the degradation of low molecular weight components. The phenolic network, consist of polycyclic, graphitic-like aromatic structures, is highly compressed and resulted in carbon-rich residue, therefore, phenolics resins exhibited the higher limiting oxygen index (LOI) value of 32. This specific properties has also directed to the progress of tradition carbon-carbon composites in which the phenolic is purposefully pyrolyzed to form a high residue carbon-carbon composites, which, possesses the enormously higher thermal stabilities (service temperatures over the 2200°C). Even though remaining tradition polymers in terms of prices, the promising thermal and FST performances exhibited by phenolics have much-admired them for utilized in aerospace interiors including flooring, panels, and partitions.

One of the major drawbacks, the brittleness behavior of phenolics restricted their usage in various applications when the structures are exposed to higher amounts of stress and fatigue. This might be overwhelmed by hybridization using elastomers including amine-terminated butadiene liquid oligomer Hypo RLP (Nanoresins, Geesthacht, Germany), carboxyl-terminated

Scheme 5 Schematic representation for polycyclotrimerization of cyanate esters.

Scheme 6 Preparation and cure of phenol-formaldehyde resins (resoles and novolacs).

butadiene liquid oligomer or silicones (Hypro CTBN 1300 $\times$ 8 (Nanoresins)), and silicone copolymer comprising 40 wt% silicone (Albiflex H 1083 S1 (Nanoresins)) in the form of toughening/flexibilizing agents.

Polybenzoxazines in Aerospace Applications

Polybenzoxazines (PBz's) emerged as one of the superior substitute to conventional phenolics including novolac/resole for the past 3–4 eras. Although PBz's (**Scheme 7**) show structural resemblance to traditional phenolics by some means, the tertiary amine functional deviate the structure and bring the strong inter and intra molecular hydrogen bonding that manage several advantages. These resins display good thermal stability, higher mechanical stability, chemical resistance, low moisture adsorption, minimal or no shrinkage during curing, high residue char, high T_g , and high operating temperatures (Kiskan, 2018; Ghosh *et al.*, 2007; Ishida and Froimowicz, 2017; Ishida and Agag, 2017; Santhosh Kumar and Reghunadhan Nair, 2010; Devaraju *et al.*, 2019). Hence, PBZs have been utilized in several applications in various industry including blends, composites, alloys, printed electronic circuit boards, and etc.

Scheme 7 Scheme for the preparation of polybenzoxazine.

Bi-functional based PBZs have been already commercially prepared by Huntsman, Gurit, Henkel, and Shikoku Chemicals (Hamerton and Kratz, 2018). Huntsman is one of the foremost industry that constantly involved in the development of benzoxazine resins since 1994 specifically for aerospace sectors. Accordingly, this company traded five various types of benzoxazine resins mentioned in Table 9 including with its conventional names and key characteristic properties namely reactivity, viscosity, thermal, and flammability properties (Black, 2004). As perceived from Table 9, these commercial benzoxazines reveals higher T_g , which are significant for aerospace sectors. In addition, mono-functional benzoxazines including aniline and phenol based benzoxazine are also manufactured by Huntsman and exported in the trade name of RD 2007-027 (Mw of 211) and RD 2009-008 (Mw of 419). Though, these benzoxazines are not appropriate for aerospace sectors; thus, they are profitable as benzoxazine accelerators be utilized as a catalyst for homo-polymer benzoxazine and co-polymer in combination with benzoxazine and epoxy. The benzoxazine accelerators are commercially traded with the name of Accelerator DT 300 (mp - 154–156°C) and DT 310 (mp - 127–134°C).

According to Huntsman, benzoxazines are ultimate for various applications including aerospace primary and secondary components such as bulk-heads, interior panels, lavatories, galleys, and table trays. In transport, these benzoxazines might be utilized as automotive components including frames, hood components, panel body, and structural assistances for buses, trucks, and light rail cars. Also, benzoxazine have probable applicability in gas/oil sectors as composites risers, pipes, down hole plugs, and vessels with high-pressure, besides its used as free from halogen laminates in microelectronic application for PCBs. Gurit is a foremost prepregs dealer for aerospace interiors and an innovative aviation sector later 1985. This dealer offered prepregs based on benzoxazine resins for aerospace interiors, traveler, and consignment floors. These prepregs (trade name as PB1000) are free from formaldehyde, and most appropriate wherever environmental standards similar to AIRBUS AP2091 are essential. The polymerization temperature of benzoxazine is as lower as 140°C for 45 min. The polymerized products are free from voids and fulfill the international fire protection (JAR/FAR) guidelines. As per the Gurit, PB1000 be able to utilize as a substitute for phenolics. For example, flexural strength is observed as 320 MPa for PB1000 filled fabrics of 550 this was good comparable to phenolics used for aerospace structures. Furthermore, PB1000 impregnating E-glass fabrics is also commercialized by them. The materials are lightweight with good mechanical and high flame resistance, low smoke, and minimal toxicity (FST) values. This benzoxazine composites might be applicable in both railway and aerospace sectors.

Self-Sensing Composites for Aerospace Applications

Self-sensing polymer composites are ability to sensing their damage, temperature, strain, and etc. (Rana *et al.*, 2014; Wang and Chung, 2013). Presently, self-sensing polymer based composites are received much distinctive consideration for numerous structural applications to ensure better safety aspects. At present, most of the case external sensors are used to distinguishing the status of structural parts. Fiber-optic and piezoelectric sensors are commercially available sensors to detect the damage and strain. Though, these sensing methods have certain intrinsic shortcomings such as high cost, fragile nature, need of expert personnel, inconvenience to isolated places and etc. To overcome these glitches, self-sensing polymer composites are growing in distinction. These composites are ability of sensing damage or strain in the structural components.

Self-sensing polymer composites typically work on the piezo-resistive principle i.e., alter their electrical resistivity with damage or strain. These composites comprise with the conducting filler such as carbon fibers, carbon particles and carbon nanotubes. The alteration of electrical resistivity is owing to the alteration in electrical connection points among the conducting components. Electrical resistivity increased over the tensile loading, this may be owing to the decrease in electrical connection points among the conductive fillers (Rana and Fangueiro, 2016). While composites are exposed to compressive loading the electrical resistivity is decreased. Conversely, in case of long conducting fiber reinforced composites indicated the reduction in resistivity while tensile loading owing to conducting fiber orientation and also more in electrical connection points. Since fiber polymer composites are generally utilized in aerospace and other sectors, evolving long fiber polymer composites with good sensing ability is challenging. Recently, hybrid polymer composites of carbon and other non-conducting fibers have been established to perform detecting the damage of composites. These composites are able to indicate the sharp alteration in the resistance as well as the fracture of the

Table 9 Commercialized benzoxazines by Huntsman corporation

Benzoxazine structure	Trade name	Viscosity at 120° C (cP)	Reactivity at 190° C (min.)	T _g (°C) from DMA	UL-94 (s)
	Araldite® MT 35600	<1000	~15	~180	>250
	Araldite® MT 35600	<1000	~20	160–170	75–100
	Araldite® MT 35600	3000–3500	5–10	230–240	<50
	Araldite® MT 35600	2000–2500	1–2.5	170–180	100–125
	Araldite® MT 35600	3500–4000	10–15	~140	>250

composites. Though, this can accomplish strain sensing by appropriate sensitivity in the pre-stressed situations. To overwhelm this issue, carbon particles or CNTs have been utilized to accomplish the good sensing enactment. The CNT reinforced polymer composites can able to detect even damage at micro-scale in composite parts and, consequently, are highly favorable for self-sensing of aerospace applications.

Self-Healing Polymer Composites for Aerospace Applications

Self-healing polymers are able to repair the destruction commenced within their structure spontaneously (Rana and Figueiro, 2016; Blaiszik *et al.*, 2010). The self-healing of destruction may be extrinsic, i.e., the composites comprise an exterior healing agent for destruction repair. The healing agent can be enclosed within the microcapsules, hollow fibers/or vascular networks. Owing to beginning of cracks, these structures that comprise healing agents breakdown, liberating the healing materials and revamping the damages. Fig. 3 displays the self-healing mechanism based on microcapsule.

Typically in epoxy matrix composites diverse types of microcapsules are prepared and used as self-healing agent. Generally, urea-formaldehyde are used for the production of microcapsules (Blaiszik *et al.*, 2008; Brown *et al.*, 2003; Yang *et al.*, 2012, 2011; Coope *et al.*, 2011; Guadagno *et al.*, 2010). Microcapsules prepared using triethylenetetramine (TETA) for wear-resistant (Khun *et al.*, 2014) and poly (methyl methacrylate) (PMMA) microcapsules for high thermal and storage stability (Li *et al.*, 2013), are prepared and utilized. Numerous encapsulation methods are used to develop self-healing materials. Though, the research has mostly motivated on meltable dispersion, interfacial and in-situ encapsulation methods. Meltable dispersion, healing agents are dispersed in the melted polymer to prepare the micro-capsules after solidification (Rule *et al.*, 2005). Interfacial and *In-situ* polymerization methods are used for preparation of urea-formaldehyde or TETA microcapsules. In this method, the shell is prepared by polymerization at the interface of healing agent droplets and the oil-in-water emulsion. The synthesis of nano-capsules using an ultra-sonication approach can also be attained. The common techniques of healing is depicted in Fig. 3.

Self-healing also can happen by numerous intrinsic mechanisms. In intrinsic self-healing, the developed with certain polymer composites which be able to reveal reversible connections by certain external triggers such as light, heat, radiation and etc., Consequently, upon beginning of damage, the external triggers can prompt diverse sorts of reversible connections (eg, a reversible chemical bonding like Diels-Alder (DA) and retro-Diels-Alder (rDA) reactions (Scheme 8)), reversible physical connections in ionic polymers, supramolecular attractions, shape memory connections etc. and repair the flaws. The healing effectiveness of polymer composites is calculated by the following equation: Numerous revocable chemical reactions are discovered for self-healing applications. The most widely studied chemical reactions are the rDA. Scheme 8 shows the self-healing mechanism of

(Eds.), 2016. *Advanced Composite Materials for Aerospace Engineering Processing, Properties and Applications*. Woodhead Publishing Series in Composites Science and Engineering. Elsevier, from Elsevier.

Scheme 8 Diels - Alder (DA) reaction mechanism for cross-linked polymers.

DA-rDA reaction of polymerization and damage for cross-linked DA polymers. [Chen *et al.* \(2003\)](#) reported the self-healing ability of maleimide and furan polymers. BMI tetrauran can be utilized to make a thermally triggered self-healing carbon fiber composites, through the DA reaction and electrical resistive heating of carbon fibers ([Park *et al.*, 2010](#)). This composites exhibited almost 100% strength retrieval under definite circumstances.

$$\text{Healing efficiency} = \frac{f_{\text{healed}} - f_{\text{damaged}}}{f_{\text{virgin}} - f_{\text{damaged}}}$$

Where f is the property of interest. The self-healing composites be able to repair the subsequent properties:

- (1) Fatigue property,
- (2) Fracture property,
- (3) Impact energy,
- (4) Corrosion and barrier property.

Polymer Nanocomposites for Aerospace Applications

Polymer nanocomposites (PNCs) have attracted considerable devotion in aerospace sectors over the few decades. PNCs comprising of both polymer matrix and nano-reinforcement dispersed into polymer matrix. Nano-fillers might be of different natures (nano-platelets, nano-tubes/nano-fibers/nano-wires, nano-particles, and fullerenes), and with at least one measurement need be in

Fig. 4 Evolution of materials for aerospace structures.

Table 10 Commonly used nano-materials and their efficient properties related to aerospace applications

S. No	Functional properties	Nano-materials
1.	Mechanical and scratch resistance	Al ₂ O ₃ , SiO ₂ , ZrO ₂
2.	Antimicrobial	CuO, TiO ₂ , ZnO
3.	Gas barrier	Nano-clays, graphene
4.	Corrosion	Nano-clays
5.	Conductivity	Graphene, CNTs, SnO ₂
6.	Fire resistant	Nano-clays
7.	Heat (thermal) stability	CNTs, ZrO ₂
8.	Ultraviolet stability	TiO ₂ , ZnO, BaSO ₄ , CeO ₂ , graphene
9.	Impact properties	SiO ₂ , TiO ₂ , CaSiO ₃ , Al ₂ O ₃ , CNTs, clay

1–100 nm range. Nano reinforcement offers very good interfacial area for superior adherence to matrix which eventually leads to greater enrichment on the property of PNCs. Unlike traditional filler reinforced polymer systems, PNCs need comparatively and significantly lower loadings of nano-fillers. Owing to its high surface area and high aspect ratio, the small amount of nano-materials are reinforced in to polymer matrix, which greatly enhance the composites properties, which reduce the further weight of the product which creates them a vital aspirant for aerospace uses. Besides, nano-material-based polymer nano-composites can offer numerous multifunctional behaviors including better thermal stability, good fire resistance, good electrical properties, optical properties, field emission, improved durability, good impact properties, and etc., which are mostly substantial for aerospace applications (Rana and Fangueiro, 2016; Thostenson *et al.*, 2005b). Fig. 4 designates the progress of materials used for aerospace structures. Recently, studies have revealed the prospective enhancement in the performance and properties of nano-reinforced polymer materials in which nano-scale materials including clay, silica particles, single-walled and multi-walled carbon nano-tubes (SWCNTs and MWCNTs), graphene, metal nano-particles and etc., are incorporated.

However, these polymer nano-composites can't able to meet the strength desires for primary aerospace components. Although certain nano-materials such as CNTs and CNFs have extraordinarily good mechanical stability than the traditional reinforcing materials similar to carbon fibers, the restriction on attaining a high volume fraction of nano-materials in composites does not permit them to attain high mechanical strength comparable to those of traditional fiber-reinforced composites (Rana and Fangueiro, 2016; Rana *et al.*, 2015). At high volume portion, nano-materials are exceedingly problematic to disperse within the polymer matrix and attempt to agglomeration, creating voids and flaws in the resulting composites. So, the easy technique to attain good mechanical strength with multifunctional behavior is to progress hybrid composites that combine both traditional and nano-reinforcements. Numerous studies on polymer nano-composites (PNCs) have been revealed that nano-fillers can deliver several functional properties (Rana and Fangueiro, 2016). Table 10 lists certain of the nano-materials with possible functional properties for aerospace uses.

The Air Force Office of Scientific Research (AFOSR, USA) newly underwrote a project to examine how the nano-fillers can increase the erosion resistant properties and heat transfer performances of solid rocket nozzle ablatives. They tried with three types of nano-particles including cloisite montmorillonite (MMT) nano-clay, carbon nano-fibers and polyhedral oligomeric silsesquioxane (POSS) were used as nano reinforcement in to resole-type phenolic matrix. All the nano-composite trials, composed with an standard ablative material, were employed in a lab scale solid rocket motor device skillful of making an exhaust plume with abrasive aluminum oxide particles, with flame temperatures $\sim 2200^{\circ}\text{C}$ and plume velocity of roughly 2000 m/sec. Data resulted from the nano-fillers reinforced nano-composites exhibited enhanced erosion resistance properties. Carbon nano-fiber reinforced nano-composites indicated the lowest erosion rate of 28% than that of other nano-composites systems. Heat-soaked temperature measurements also are lesser in the case nano-composite systems when compared to the standard ablative material. Polymer nano-composites grasp great potential for forthcoming high-temperature applications though the utmost task is to choose the nano-particles with good compatibility with polymeric resin (Black, 2004).

Summary and Conclusion

The use of polymer matrix based composites in the aerospace sectors are increasing progressively owing to numerous added benefits of composites over the metals, including reduction in weight, good strength, good resistance to corrosion and greater fracture and fatigue properties with less fuel consumption. The present article provides an overview of several types of polymer matrices including both thermosetting and thermoplastic polymers, various reinforcements including glass/carbon/Kevlar/aramid fibers and their properties including advantages and disadvantages for making aerospace primary and secondary structures. The article also discusses the necessity and importance on developing consistent self-healing and self-sensing composites to prevent the repairs and to increase the safety aspects and service life of aerospace components. Nonetheless, it can be projected that polymer matrix materials with vast flexibility in terms of structural materials and properties will substitute the metal components in the future aerospace applications. Moreover, the modern generation of traveler air-crafts has incorporated a larger amount of composite components in primary aerospace structures, assembly up to $> 50\%$. The development of bigger parts with better complexity, to report the higher production volumes in these modern generation composite aircraft, needed substantial revolution in the arena of polymer composites.

Introduction

Automotive industry represents an important sector of the world economy and a large end-use customer market for the polymer industry, which has resulted in increased production and quality of these materials. In 2017, the market for global automotive composite materials was estimated around \$4.3 billion, one and a half its value of \$2.8 billion in 2011 (Kazmierski, 2012), which represents a substantial growth for the world chemical and composites industries. According to a recent report by the Economics & Statistics Department of the American Chemistry Council (American Chemistry Council, 2019), only the North American Free Trade Agreement (NAFTA) light vehicle industry was valued around \$431 billion in 2018. The 16.81 million light vehicles assembled in the United States, Canada and México in that year required about 2.6 billion kg of plastics and polymer matrix composites (PMCs) valued in \$7.7 billion, or \$458 per vehicle. This is in line with the trend for higher fuel efficiency and lower gas emissions in vehicles, which is partially achieved by using more and more lightweight materials such as aluminum, magnesium and PMCs to replace heavy metals, such as iron and steel in different automotive components. As a reference, the total weight of a lightweight vehicle in 2008 comprised 7.8% of aluminum and 8.4% of PMCs meanwhile the total weight of a vehicle in 2018 had 10.7% of aluminum and 8.8% of PMCs. The use of PMCs in light vehicles has increased from less than 9 kg per vehicle in 1960 to about 160 kg per car in 2018 distributed in more than 1000 components (American Chemistry Council, 2019). In the same line, demands from European Union legislation have promoted the production and use of vehicles with increased fuel efficiency and lower emissions (from <130 g CO₂/km in 2015 down to <95 g CO₂/km by 2021), which is being mainly attained by vehicle weight reduction using PMCs. The use of these light materials allows a reduction of weight in the range of 15%–25% in the case of glass-fiber reinforced composites and 25%–40% for carbon-fiber reinforced composites (Suschem, 2017).

The light vehicle market presents significant opportunities for plastics and composites. The trends of world automotive industry to move up to self-driving electric vehicles and ride-sharing electric platforms will demand for increased safety and new vehicle architectures, which will create new exclusive opportunities for plastics and composites, fostering their production this way. Currently, the most typical PMCs found in cars, minivans, pickups and SUVs are made of a polymer matrix, commonly polyester, polyurethane, epoxy, polypropylene, nylon, or other resin, and fibrous reinforcements made of different materials such as glass, carbon, aramid, etc. The fibers provide strength and stiffness while the matrix protects, and transfers loads between fibers. This synergy allows the production of materials with superior attributes to those found in polymers or fibers alone. Thus, it is possible to find PMCs in different automobile parts such as the exterior body and interior components, safety devices and structures, electrical systems, chassis, fuel system, powertrain and engine components in today's vehicles. The latest are the most complex and complicated parts since they are not only subjected to stress, vibrations, fatigue and environmental changes, but also to friction and wear, and are exposed to chemical fluids such as combustible, lubricants and coolants.

PMCs used in components to be exposed to friction and wear during operation are known as tribological PMCs. These can be formed by molding or casting, injection molding or vulcanization to provide lighter, cheaper, quieter and corrosion and wear resistance components for vehicles (Fox, 2016). Basically, in the case of tribological composites, the matrix provides the bulk mechanical properties and the service temperature while the reinforcements, apart from improving stiffness, impact resistance, thermal conductivity and creep resistance at high temperatures, they are intended to improve wear resistance and reduce friction coefficient (Friedrich *et al.*, 1995) by lowering adhesion and rising stiffness and strength (Friedrich, 1997; Reinicke *et al.*, 1998; Aldousiri *et al.*, 2013).

Polymers may be roughly classified into three classes according to their physical properties, operation temperature range and cost, these are commodity, mid-range and high-performance polymers (Fox, 2016). Commodity plastics such as polystyrene, polyvinyl chloride, polypropylene and polyethylene in its various forms are relatively weak materials with tensile strengths in the order of 20 MPa and operating temperature range below 100°C. The mid-range polymers, commonly referred to as engineering polymers, include materials such as polyamides and polyesters as polyethylene and polybutyl terephthalate with strengths up to 75 MPa and continuous operating temperatures up to 120°C. Finally, the third class, or high-performance polymers, are polymers with strengths in the range of 100 MPa and operating temperature of hundreds of degrees (<427°C) along with a series of outstanding physical properties as high melting point and excellent resistance to degradation. The most remarkable examples of these polymers are polyaramids (e.g., Kevlar) and the polyaryletherketone family which includes polyetheretherketone and polybenzimidazole. Currently, engineering and high-performance polymers (both thermoplastics and thermosets, and elastomers) reinforced with fibers are the most used to produce a number of different tribological polymer composites for automotive components such as tires, seals, gears, dry sliding bearings, rolling bearings, brakes and clutch materials, paint coats, etc. For the sake of space, this article is limited to tribological components made of PMCs apart from those of the interior of modern internal combustion engine and battery electric vehicles, some of which can be identified in Fig. 1(a)–(b).

Fig. 1 Typical tribological components made up of PMCs in (a) combustion engine vehicles; (b) battery electric vehicles.

Tribology Fundamentals of Polymer Composites

Friction is defined as the resistance encountered by one body in moving over another either in sliding or rolling motion. To slide or roll one body against the other, a tangential force, F , is needed, which is known as the frictional force. The ratio between the frictional force and the normal load, W , acting on the bodies is known as the friction coefficient, μ , given as:

$$\mu = \frac{F}{W} \quad (1)$$

The friction coefficient is dependent on many factors as surface roughness, temperature, humidity, mechanical properties of contacting materials, lubricant and lubrication type. High values of μ are undesirable in most of engineering applications since they lead to unacceptable high friction forces that result in significant energy losses, heating and wear. Polymers typically exhibit

Fig. 2 Schematic representation of a p - v chart emphasizing the safe operating region for a polymer.

Fig. 3 Schematic representation of a typical Stribeck's curve.

low coefficients of friction (COF), with values ranging between 0.1 and 0.5, whether self-mated or sliding against other materials (Hutchings and Shipway, 2017). This is because polymer/metal or polymer/polymer contact is predominantly elastic and, in some cases, viscoelastic.

Polymer tribology usually does not follow the classic laws of friction, since the COF of polymers varies notably according to normal load (COF decreases with load up to a limit determined by deformation and contact temperature), sliding speed (COF decreases with increasing speed up to a limit determined by heat generation and contact temperature) and temperature (COF varies for temperatures above and below the glass transition temperature, T_g) (Hutchings and Shipway, 2017). In general, fillers in PMCs generate an increase of COF, so special techniques should be applied to reduce friction in PMCs. Among the most popular solutions for this purpose are the inclusion of soft solid fillers and the addition of internal or external lubricants into a harder polymer matrix. The softer filler/polymer acts as a lubricant facilitating the formation of a transfer film at the interface between the filled polymer and a hard surface (Briscoe and Sinha, 2005). In order to identify reliable tribological conditions (sliding speed and load), and to avoid premature failures for a component made of a PMCs, pressure or load, p , versus speed, v , charts are commonly developed. An example of a p - v chart for a polymer, emphasizing the safe operating region is shown in Fig. 2. The maximum value of contact pressure or load on the curve represents the force limit while the maximum sliding speed value states the frictional heating limit for safe operation of the polymer.

Using lubricants is the most widely spread way to reduce COF between surfaces of polymers and their composites. A lubricant can be a liquid, solid or semisolid substance between the sliding or rolling surfaces used to separate them and to avoid surface asperities contact. However, the lubricant may not totally avoid asperity contacts, so different lubrication regimes may be found, these are called hydrodynamic, boundary and mixed regime, respectively. The lubrication regime is represented by the Stribeck's curve illustrated in Fig. 3. It is a graphical representation of the COF as a function of the bearing number or Hersey number, H_v , which is a dimensionless lubrication parameter defined as, $H_v = \eta U/W$, where η is the lubricant viscosity, U is the sliding speed and W is the applied load (Hutchings and Shipway, 2017). Hersey number may be also seen as the ratio between the lubricant film thickness and surface roughness. In the hydrodynamic lubrication regime, the surfaces are completely separated by the

lubricant film preventing asperities contact, while in boundary lubrication the surfaces are not separated completely, and appreciable asperity contact is generated. Mixed lubrication is the combination of both, hydrodynamic and boundary lubrication regimes at the sliding interface.

Asperity contact in sliding interfaces of materials is precursor of wear, which can be generally classified into dry sliding wear and lubricated sliding wear. Both wear types can be subclassified into abrasive and adhesive wear. Abrasive wear can take place in two different ways: two-body abrasion or three-body abrasion. Two-body abrasion is produced mainly by the action of hard asperities, either from one surface or both, while three-body abrasion occurs when separate hard particles, namely, debris and contaminant particles, are present at the sliding interface altering friction and wear. Three-body abrasion is dependent on the particles acting at the interface, these might be either fixed/adhered or dragged to one or both surfaces producing grooves or rolling at the interface. On the other hand, adhesive wear is produced predominantly by adhesion between the surfaces (Hutchings and Shipway, 2017).

A simple assessment of sliding wear is given by the Archard's wear equation (Hutchings and Shipway, 2017):

$$Q = \frac{V_w}{S} = \frac{KW}{H} \quad (2)$$

where Q (mm^3/m units) is known as wear rate or the volume worn (V_w , mm^3 units) per unit sliding distance (S , m units), W is the normal load in N units, H is the hardness of the softer surface and K (mm/m), is the wear coefficient, which represents the severity of the wear processes. In this model, it is assumed that H is equal to the yield pressure for the plastically deforming asperity, akin to that occurring in an indentation, so H has units of N/m^2 . In practice, however, the specific wear rate, k , which is given by $k = K/H$ is more often used. It represents the wear volume per sliding distance per normal load commonly expressed in $\text{mm}^3/\text{m} * N$ units. Although Archard's model was originally developed for metals, it can provide some insight into the wear of other materials, including polymers.

PMCs used in unlubricated tribological applications such as bearings, bushings, gears, etc., usually slide against harder metallic countersurfaces (Friedrich, 2018). Thus, nearly all the deformation due to contact or sliding takes place within the polymer, and the surface finish of the hard countersurface has a strong influence on the mechanism of wear. For smooth countersurfaces adhesive wear is expected in the surface layers of the polymer, while for rough countersurfaces wear results either from abrasion associated with plastic deformation of the polymer by hard asperities, or from fatigue crack growth in the deformed region (Friedrich, 2018). These two classes of wear mechanisms in polymers, involving surface and subsurface deformation have been termed as interfacial and cohesive wear processes, respectively (Hutchings and Shipway, 2017). Interfacial wear involves material removed by processes occurring close to or in the surface of the polymer, mainly, by adhesion. It occurs only when the countersurface is smooth, and there is transfer of polymer to the harder countersurface and its subsequent removal as wear debris, as illustrated in Fig. 4(a). The process is similar to that seen in metals. In steady state wear the wear rate is often directly proportional to the normal load over a large range, in conformity with the Archard's wear equation. On the other hand, cohesive wear is produced by plastic deformation of the surface and subsurface of the polymer, caused by the passage of hard protuberances on the countersurface. There may be asperities on the hard surface arising from its topography, or particles of the harder material partially embedded into a softer countersurface, or possibly protuberances of polymeric debris transferred to the countersurface (Hutchings and Shipway, 2017), as illustrated in Fig. 4(b).

Overall, friction and wear of PMCs can exhibit different behavior according to the polymer matrix (thermoplastic, thermoset or elastomer) and reinforcements. Thermoplastic and fiber thermoplastic composites are known to exhibit distinct tribological behavior from that in thermosets or elastomers. In thermoplastics, film transfer of the soft polymer surface to the metallic surface during sliding due to heating is very likely (Aldousiri et al., 2013). Friction generates heat at the sliding interface, which deteriorates the polymer surface by material detachment when temperature exceeds T_g . The addition of fillers and/or fibers usually influences the heat transfer at the interface by reducing adhesion between the asperities, film transfer and material detachments. In the case of thermoset polymers and fiber thermoset composites, the possibility of film transfer is lower than in thermoplastics since thermosets are, in general, much harder than thermoplastics (Shackelford and Alexander, 2014), reducing the possibility of plastic deformation and film transfer on the countersurface. Neat thermosets promote rougher film transfer than thermoplastics, but the surface is cooler since the frictional force is less and debris is more able to roll at the interface instead of being adhered. The presence of fibers in thermosets are useful to further assist in cooling the interface by strengthening the exposed layer of the polymer and lowering friction due to easier rolling of debris. These effects, however, may increase wear in some cases due to the transition from adhesive to abrasive wear (Aldousiri et al., 2013). On the other hand, friction in elastomers is different from most of thermosets and thermoplastics. It is because in elastomers, besides the interfacial and cohesive transfer, there is one more mode of energy dissipation called hysteresis. The hysteresis loss is characteristic of all viscoelastic materials and comes from the viscoelastic "flow" or deformation of the materials over the asperities of the hard countersurface. For smooth and dry contacts, the interfacial component can be very large in comparison to the hysteresis component; however, for rough surfaces and for smooth and wet surfaces, hysteresis loss contributes substantially to the overall frictional force (Briscoe and Sinha, 2005). In contrast to thermoplastics and thermosets, elastomers exhibit tearing as the main wear mode, even under three-body abrasion situations (Farfan Cabrera et al., 2017b). Tearing consists of a corrugated appearance feature on the elastomer surface produced by micro delaminations perpendicularly orientated to the sliding direction, which result from micromolecular fracture or repeated rupture of the polymer's molecular chains. It is generated under continuous sliding action of hard asperities of the countersurface or debris (Zhang, 1992).

Fig. 4 Schematic representation of wear processes occurred in polymers against metallic surfaces; (a) interfacial wear; (b) cohesive wear.

Classification of Polymer Matrix Composites for Automotive Tribological Applications

PMCs can be overall classified according to its composition and structural architecture (Friedrich *et al.*, 2011). They are made of a polymer matrix, which can be thermo-set, thermoplastic or elastomer, and reinforcements of a non-polymer material, the most typical being glass, carbon, aramid, natural, ceramics, etc. The reinforcement material, with continuous or discontinuous architectures may be arranged in specific order into the matrix. Depending on the architecture, matrix and reinforcement materials, different physical and chemical properties are conferred to the composites. Those composites exhibiting suitable friction, wear or lubricating properties are sub-classified, according to their application, as tribological PMCs. Apart from appropriate tribological properties, they can be designed to achieve other characteristics required to meet specific applications and exhibit enhanced performance as tribo-components (Friedrich, 2018). Therefore, tribological PMCs can be divided into self-lubricating, friction, electrically conductive, high or low temperature resistant and self-healing as shown in Fig. 5. The attributes of each of these materials have fostered development of improved products and components for the automotive industry. The description of each category and some actual examples are given in the subsequent sections.

Self-Lubricating Composites

Self-lubricating PMCs are materials created to reduce friction and wear in tribological components that may experience lubricant starvation during its operation or when the use of lubricants is not recommended. They are two-phase systems, namely, a soft phase made of a lubricant reinforcement and the polymer matrix as the hard phase (Friedrich, 2018). The main attributes of self-lubricating composites are low-noise operation over a long period of time, low shear strength in the sliding direction, high compression strength in the load direction, and low COF throughout the entire service life of the component (Sorrentino, 2018). The most common examples of automotive components for this type of composites are rolling bearings, door hinges, sliding bearings, shock absorbers and bushings of steering shaft joints and windshield wipers. Bushings are used to absorb road bumps, control the movement in the joints and reduce noise and vibration.

The composite materials for these bushings are also used as bearings or coatings for bearings in high pressure and diesel fuel injection pumps. One formulation approach for these is the polyetheretherketone plastic matrix compounded with special micro- and nano-scaled fillers to improve its tribological properties (Friedrich, 2018). On the other hand, an example of a proprietary

Fig. 5 Classification of polymer matrix composites and subclasses of tribological PMCs for automotive applications.

high performance polyimide resin (Polyamide P84®NT by EVONIK) is commercially available as a fine powder, which can be blended with solid lubricants such as graphite, molybdenum disulfide, or polytetrafluoroethylene to make self-lubricating components as bushings, seals, bearings components, guides, and gear wheels in the automotive industry (EVONIK Industries, 2011).

Natural fibers have also been investigated as potential reinforcements in self-lubricating composites. For example, polyester reinforced with kenaf particles has been found to exhibit non-abrasiveness during processing in a wear rate test. The layer transfer mechanism works at high loads and provides a significant reduction of wear and friction (Nordin *et al.*, 2013). Palm kernel activated carbon epoxy composite is another potential self-lubricating composite. It has the capability to reduce its wear rate and friction coefficient for increasing applied load and different temperatures (Mohmad *et al.*, 2018).

Friction Composites

Friction composites are materials used to generate high and stable friction. Properties of this sort of composites contrast with most desirable characteristics of all other tribological PMCs categories, in which friction reduction to a large extent is desirable. Additionally, friction composites must possess good thermal conductivity, excellent heat and wear resistances, good compatibility or weak absorbability of water, oil and brake fluids, as well as reduced propensity to produce shudder, noises and harshness (Cox, 2012). The most common applications of this type of materials in vehicles are brakes, clutches, belts and tires. Brakes use friction to decrease speed of the vehicle meanwhile clutches, belts and tires use friction to control power transmission and/or traction. The most common polymeric matrixes for brakes and clutches are made of thermosetting polymers (i.e., epoxy and phenolic) while the main reinforcements are fibers, binders, friction modifiers and fillers (Biczko *et al.*, 2017). Fibers of aramid, glass, carbon and steel are the most typically used (Briscoe and Sinha, 2008). In the case of tires and belts, they are widely made of rubber or elastomers. So, various rubber composites reinforced with fibers are being developed for enhanced performance (Visakh *et al.*, 2013). For example, tires are made of a rubber composite (raw rubber with sulfur and carbon black) and steel cords or organic fibers. The rubber, which can be neoprene, natural rubber, styrene-butadiene rubber, nitrile, etc., provides the friction required for traction while the steel cord or organic fiber provides the mechanical strength required to support the load or pressure and impacts (Ikeda *et al.*, 2018).

An important fact to consider during operation of friction materials are wear debris of different chemistries, which are toxic or show mutagenicity, that are released into the environment. So, using natural and non-toxic materials is a current trend for developing environmentally friendly materials for this application. Since asbestos were barred as a constituent to produce friction composites in 1980's due to its adverse effect on human health, several substitutes so-called "green composites" have been investigated and developed (Matějka *et al.*, 2013). For example, cellulose based fibers and plant fibers, namely, kenaf, betelnut, sisal, jute, flax, sugarcane, bamboo, etc., as well as powders of nut shells, coconut shells, hazelnut shells and palm kernel shells are being studied as potential reinforcements in friction composites (Dadkar *et al.*, 2009; Matějka *et al.*, 2013). In the case of tires, some of the most recent and successful improvements of tribological performance of elastomer composites is based on nanotechnology. For this, a series of nanoparticles, namely, silica, core/shell polymer, poly(alkylbenzene)-poly(diene), polyhedral oligomeric silsesquioxanes, carbon nanotubes, graphene, aerogels, nano-diamond and fullerenes have been used as reinforcements for the rubber matrixes (Keams and

Fig. 6 Diagram of a conductive bearing for electrified vehicles. Reproduced from Bosch, R., 2014. Conductive Lubricants Will Protect the Electric Motors of the Future. Available at: <https://www.bosch-presse.de/pressportal/de/en/conductive-lubricants-will-protect-the-electric-motors-of-the-future-42628.html> [last access: july 2020].

Baucher, 2014). The purposes of using these nanomaterials is to enhance curing as well as mechanical and dynamic mechanical properties which result in improved processability and reduced hysteresis, vehicle fuel consumption and cost. For example, the cluster-like physical structure of silica particles is suitable to arrest crack propagation during tearing by introducing tortuosity in its path, which results in higher tearing energy for crack propagation. So, silica particles may help for crack arresting during tearing, fatigue and possibly wear in a tire tread compound (Veiga *et al.*, 2017).

Electrically Conductive Composites

Tribological conducting PMCs are materials that have good friction and wear characteristics along with a certain electrical conductivity. The most common composites meeting these properties are engineering and specialty polymers reinforced with traditional fillers of intrinsically high electrical conductivity, as carbon nanofibers, multiwall carbon nanotubes, short graphite fibers, etc. (Friedrich, 2018). This type of composites offers ample possibilities for automotive applications, since combine the intrinsic properties of polymers, namely, low density, corrosion resistance and toughness with those of the reinforcements, as wear resistance, stiffness, strengths and electrical conductivity.

Conductive bearings for electro-coating processes in automotive industry, conductive ball cages and greases for bearings (Friedrich, 2018), and conductive dynamic seals for electric vehicle powertrains are the most important automotive applications of these composites (BioAge Group, 2019; Farfan-Cabrera, 2019). For example, an electrocoating process for painting vehicles requires all the components of the assembly to be electrically conductive for better performance. This helps to accelerate the painting process by facilitating attraction and deposition of painting particles in the car body and produce a continuous film over every surface until the coating reaches the desired thickness (Friedrich, 2018). In the case of conductive bearings, greases and dynamic seals, they are developed to avoid failures in electric motors and transmissions due to surface damage or wear caused by electrical discharges. This phenomenon, illustrated in Fig. 6, and technically known as electrical discharge machining or spark

Fig. 7 Dry film lubricant coatings on the head of the piston (slick lubricant). Reproduced from JCM Automotive Machine Shop and Coatings, 2011. Available at: www.jcmmachineandcoatings.com. [online] Available at: <https://www.jcmmachineandcoatings.com/coatings/pistons/> [last access: July 2020].

machining, is a problem in electrified powertrains. At present, electric vehicles operate with 12 volts to provide all conventional automotive electric systems with enough power. This voltage, however, may change to 48 volts to support a growing number of functions in vehicles in next few years. Higher levels of voltage will result in stronger alternating electric fields in alternators and electric motors causing electrical discharge in the ball bearings. Produced sparks can melt tiny areas of the metal's surface generating irregular raceways, and consequently, noise and premature failures. So, bearings and seals should be electrically conductive (Bosch, 2014). Conventional seals are made of insulating polymeric materials and are not suited for this purpose. Hence, new conductive seals made of elastomer matrix with special conductive fibers are being developed (BioAge Group, 2019). As for conductive greases, these are formulated with a high percentage of conductive powder of various natures, conveyed in synthetic oils/silicone. Another example is a gel-based polyester thickened with carbon black. The fundamental characteristics of these greases are their low volatility, high thermal stability at high temperatures, high spread ability and electrical conductivity (Technolube-Seal, 2017).

High-Temperature Resistant Composites

High-temperature resistant PMCs are materials able to operate at elevated temperature while keeping their tribological properties. This sort of composites, qualified to provide dimensional stability and long-term durability when exposed to hot environments, consist of a polymer matrix with high T_g and reinforcements with flame retardancy. Typical matrix polymers for this application are thermosets, as epoxy and thermosetting polyamides, and thermoplastics, as polyimides and polyarylene ethers, such as polyetheretherketone and polyethersulfone; meanwhile reinforcements may be of continuous aligned, glass, carbon or ceramic fibers. Short fibers and whiskers are not often used for this application, although enhanced tribological behavior has been reported for polyetheretherketone and polyetherimide reinforced with short carbon fibers, graphite flakes, and sub-micro particles of TiO_2 and ZnS under dry sliding (Chang *et al.*, 2007).

The highest temperature in a vehicle takes place inside the engine, affecting tribological components such as the crankshaft bearings and pistons, which may reach temperatures up to around 300°C. Conventional aluminum alloys can cope with this requirement, but request for lighter materials opens a novel possibility for polymer composites. New high-temperature resistant composites are being used for coatings of such bearings and pistons (see Fig. 7). Currently, there are various polymeric candidates suitable as matrices for coatings in these applications, examples of these are polyethersulfone that possess a service temperature above 290°C and excellent corrosion resistance, polytetrafluoroethylene and perfluoroalkoxy alkanes which have a service temperature about 260°C, low COF and high wear resistance (Pei *et al.*, 2016). In addition, polytetrafluoroethylene has self-lubricating properties (Myshkin *et al.*, 2015), which make it suitable as matrix or reinforcement (Chaudhari, 2013). Polybenzimidazole is of great interest for companies due to its excellent thermal, mechanical and tribological properties (Tanaka *et al.*, 2006), with good wear resistance, excellent substrate adhesion and high fatigue resistance (Samad and Sinha, 2010). Polyamideimide, also named as Torlon from Solvay S.A., company, is compounded with solid lubricants as MoS_2 or graphite to improve the tribological behavior for piston coatings and crank shaft bearings. Another example is the aforementioned polyimide resin (Polyimide P84NT®), which has a high T_g and high deflection temperature, making it appropriate for high-temperature composites.

The DSM company (Evansville, Ind.) developed a polyphthalamide with glass transition temperature up to 160°C, the commercial name is Stanyl ForTii®. It is a composite with several grades up to 60% of glass fiber content (DSM, 2018). The high

polymer crystallinity of Stanyl ForTii® provides excellent wear-resistance and has been used in thrust bearings, bushings, chain guides and timing chains of vehicles at operating temperatures up to 180°C (Legault, 2012).

Within the bioplastics currently available on the market, some materials are already validated for high-temperature applications. The bio-based polyamides exhibit good properties, namely, high wear resistance, good heat resistance, chemical resistance to oils and solvents, and fire resistance (Kohan *et al.*, 2003), which make them suitable for under-the-hood components such as air cleaner, throttle valve guards and throttle valves in automobile engines. Several bio-based PA's, which are derived from renewable feedstocks, such as castor beans and sugar cane, have also appeared on the market. The automotive applications of these commercial bio- polyamides and their glass-fiber composites also include charge air duct for engines. Rilsa-® HT Polyamide 11 from Arkema, for instance, is used in the exhaust gas recirculation tubes instead of those made of metallic materials, such as aluminum, for Peugeot and Citroën vehicles (French cars brands of Groupe PSA) (Arkema Group, 2009).

Low-Temperature Resistant Composites

Low-temperature resistant PMCs are materials able to operate at cryogenic temperatures ($< 150^{\circ}\text{C}$) while keeping their tribological properties. To have a proper tribological performance under this extreme environment, these composites should possess good heat dissipation or high heat conductivity, specially at the sliding contact regions, the matrix and reinforcements must have similar thermal expansion coefficients to limit thermal stresses in the boundary surfaces of the components, low chemical reactivity with cryogenic fluids and ductility at low temperatures. In general, the friction coefficient of polymer matrix composites can be reduced, even at low temperatures, by increasing their thermal conductivity (Friedrich, 2018). The most promising candidates for this purpose are polytetrafluoroethylene and polyetheretherketone composites, since they have been successfully used in other cryogenic applications as in rockets (Fusaro, 1990; Theiler and Gradt, 2013). They present outstanding tribological properties in both, room and low temperatures. The most common reinforcements used for these composites are glass and carbon fibers.

The development of new applications of cryotechnology in the automotive industry is underway, for example, in superconductors for zero friction bearings (Mukoyama *et al.*, 2017) and zero emissions hydrogen combustion engines (Gurz *et al.*, 2017). The use of this technology requires materials able to withstand cryogenic temperature and exposure to extreme environments with helium, cryogenic liquids or vacuum without losing performance (Friedrich, 2013). The most critical tribo-components in hydrogen combustion vehicles are bearings, dynamic seals and valves for pump and injectors. Also, external tribological hardware having high-performance in cryogenic environment, namely, pumps, valves and seals, is required for refueling, servicing and maintenance processes of such vehicles (Gurz *et al.*, 2017). The temperature existing in hydrogen engines is significantly lower than in gasoline or diesel internal combustion engines. So, most semi-crystalline polymers could be also used to substitute different tribological parts into the hydrogen engine, which are not subjected to cryogenic temperatures, but to lower temperatures than those of gasoline or diesel combustion engines (Stead *et al.*, 2019). Considering that conventional lubricants are not recommended to be used at cryogenic temperatures, self-lubricating polymers and composites are considered as the future trend for producing low-temperature resistant PMCs.

Self-Healing Composites

Self-healing PMCs are materials that may recover their properties after damage, without external intervention. The most popular application of this kind of composites is in automotive paint coatings. The term “coating” implies any thin layer covering another material. The protective function of the coating is related to the underlying substrate (automobile metal body), it must be sealed off from external environment such as light, humidity, air, dirt, chemicals, mechanical abrasion and corrosion. The coating damage can be seen as the immediate loss of its protective function induced mainly by internal microcracking, which dramatically truncates the lifetime of the coated structures. The detection and repair of the inside damages in the materials was relatively impossible till the discovering of self-healing materials. They are made by the embodiment of encapsulated or enclosed micro- or nano-sized healing agents into a polymer matrix. It is to isolate and protect the agents from the external environment (Kanu *et al.*, 2019). The healing mechanism starts when the enclosed micro/nano capsules in the host material break and cause releasing of the healing agents through the generated cracks by capillary phenomena. Then, the released healing agent solidifies by a polymerization reaction with the active materials inducing polymerization in the host matrix. Also, it cures after reacting with the already embedded catalyst or with oxygen to seal the created cracks (Ataei *et al.*, 2019). One relevant example of a composite exhibiting outstanding self-healing properties is the epoxy resin enclosing encapsulated dicyclopentadiene and Grubb's enzymes. When dicyclopentadiene associates with the Grubbs' enzymes, which is diffused in the epoxy resin, a ring like opening metathesis polymerization is initiated and a cross-linked tough polycyclopentadiene is thereafter formed to heal the damage (Kanu *et al.*, 2019). Apart from dicyclopentadiene and Grubb's enzymes, other materials have been demonstrated as healing agents for epoxy resins, for example, epoxy and amine, mercaptan, phenylacetate, ethyl phenyl acetate, chlorobenzene, linseed oil, tung oil and alkyd resins (Ataei *et al.*, 2019; Adekunle, 2015; Suryanarayana *et al.*, 2008). Regarding developments and applications of self-healing composites in the automotive industry, the Nissan Motor Co. Ltd developed a paint coating with the potential of self-healing upon exposure to wear and several chemical media (Bentham *et al.*, 2007). This material is based on epoxy resins with high thermo-mechanical performance, excellent adhesion, good chemical resistance, and corrosion resistance. The recovery time has a close relationship with the depth of the scratch and temperature in the surrounding environment.

Fig. 8 Typical tribological tests for evaluating PMCs.

Typical Tribological Tests for Automotive Polymer Matrix Composites

The definitive evaluation of PMCs to give them reliable tribological applications require their full-scale testing in situ, where entire components are subjected to actual operating environments. In such a way, accurate assessment of useful life and tribological performance can be determined. This, however, may be excessively expensive and time-consuming, so most researchers and manufacturers prefer less complex tribological testers to approach realistic critical wear and friction conditions. Thus, the friction and wear behavior of polymer matrix composites for automotive tribological components can be evaluated by several short and low-cost tribological tests. The most common tribological tests are illustrated in Fig. 8, they can be conducted under dry or lubricated conditions depending on the specific application of the material. The pin-on-disk, reciprocating, block-on-ring, micro-abrasion, pin-on-drum and dry sand rubber wheel testers can be used for unlubricated tests, while the first four are often used for both lubricated and unlubricated tests. Each tester is capable to reproduce certain controlled tribological conditions, namely, lubrication type, sliding motion and distance, applied load, speed, abrasive environment, temperature, etc., generating measurable wear losses in the tested materials and, in most cases, providing COF measurement. Hence, selecting the most suitable test for evaluating PMCs for tribological applications is crucial for achieving the most realistic approach. A brief description of the aforementioned tribological tests is given below.

Pin-on-Disk Test

The pin-on-disk is considered as one of the most common test for friction and wear characterization of materials due to its low complexity and the capability to reproduce a wide range of lubricated and unlubricated automotive tribo-contacts, such as those of brakes, dry and wet clutches and sliding bearings. The standard configuration of this device allows testing of PMCs under unidirectional sliding, but most modern devices enable testing of materials under other different sliding motion modes including bidirectional and fretting, at controlled speed, time, temperature, humidity, vacuum or load. The test's name comes from the type/geometry of specimens promoting the tribo-contact. In this case, one specimen is a pin that can be flat or spherical (ball) while the other is a disk. Usually, the pin is fixed to an arm that is weighted down onto the disk sample with a certain load. The disk sample is rotated at a controlled and predefined speed. The arm and the pin fixation allow alignment and stable position in the friction track formed by the pin on the disk. The friction force generated by sliding of the pin on disk can be measured and recorded by load or torque sensors installed in the machine. Wear rates can be estimated for both, the pin and the disk, by measuring the weight loss and/or wear volume generated during the test. Pins made of the polymer composite and metallic disks are the typical type of samples tested using this machine. ASTM G99, ASTM F732 and ISO 7148-2 are examples of standard methods suggested for evaluating wear and COF of polymers.

Linear Reciprocating Test

The linear reciprocating tribometer was developed to evaluate the tribological properties of bulk materials, coatings, lubricants and additives which are to be subjected to a reciprocating sliding in their actual application. It allows determination of wear rate and COF of PMCs in lubricated or unlubricated contacts in a wide range of operating conditions, such as load, temperature, frequency and stroke length. Most modern testers can reproduce fretting wear conditions, extreme environments and larger amplitude linear sliding conditions. In general, it can accommodate a variety of sample geometries to create point, line and area contacts being mainly suitable for automotive tribo-components, namely, piston/cylinder liner, shock absorbers, ball joints, etc. The test can be configured in a ball-on-plate or pin-on-plate arrangements. Both consist on positioning a ball or pin perpendicular to the plate and apply a predefined load against the plate. Either the pin or the plate is moved in a linear reciprocating way at a fixed frequency. Friction force is measured during the test via a load cell installed in the tester. Wear rates can be estimated for the pin and the plate by measuring weight loss and/or wear volume generated during the test. Either pins or plates made of the PMC can be prepared and tested using this machine. ASTM G133, ASTM F732 and ISO 19291 are the typical standard methods used to determine wear rate and COF of polymers under reciprocating sliding.

Block-on-Ring Test

The block-on-ring test is a simple method commonly used to assess the tribological behavior of a wide range of solid materials, including PMCs under different sliding conditions and environments, namely, time or sliding distance, load, speed, temperature, humidity and lubrication. Basically, it consists on loading a block, which is usually made of the PMC to be tested, against a rotating metallic ring with a predefined load. Since lubricated and unlubricated tests can be performed in this device, the common automotive tribo-contacts approached by using this tester are those present in sliding bearings and brakes where the predominant wear patterns are produced primarily by abrasion. The frictional force generated by the sliding between the block and ring samples is measured and acquired via a load cell installed in the tester, meanwhile the wear rate of either the block or ring is estimated by measuring the material mass or volume loss generated during the test. The ASTM G77 and ISO 7148-1 procedures are the typical standard methods to perform this test.

Micro-Abrasion Test

The micro-abrasion wear test is a method relatively new for characterization of wear rate and resistance of a wide range of materials, namely, ceramics, metals, coatings, polymers and PMCs. The test is suitable for materials used in automotive components subjected mainly to mechanisms of rolling and grooving abrasion, for instance, dynamic seals, ball joints, paint coatings and journal bearings. The method was introduced by Rutherford and Hutchings in 1997 ([Rutherford and Hutchings, 1997](#)), thereafter, a significant amount of work has been done to improve the test reproducibility and to implement it as a standard wear test for tribological materials ([Gee et al., 2005](#)). The aim of the test is to generate a small wear crater with ellipsoid or spherical cap geometry and defined wear patterns (micro-indentations and/or grooves) on small and thin flat specimens. In the test, regularly, a 25.4 mm rotary ball, which can be made of steel, stainless steel, ceramics or polymers, is loaded against the PMC sample at a predefined load, speed and ball cycles while a slurry containing abrasive micro-particles is supplied at the contact. The typical slurry used for this test is made of silicon carbide (SiC) micro-sized and angular particles (4–8 μm) dispersed in distilled water at a concentration of 80 gr/100 ml. However, other abrasives, namely, silica sand, aluminum oxide (Al_2O_3), sodium bicarbonate (NaHCO_3), glass, etc., can be used. Ball rotation speed and cycles, load, slurry feed flux and concentration can be varied depending on the tribo-contact to be replicated. In up-graded micro-abrasion testers, lubricated conditions can be also reproduced, and COF can be measured during the test by additional sensors installed in the device.

Pin-on-Drum Test

The pin-on-drum test, also known as high-stress abrasive wear, was made to produce and evaluate two-body abrasive wear behavior of bulk materials, including, polymers and PMCs. Basically, one end of a pin specimen is translated linearly over the surface of a rotating drum, which is covered with an abrasive paper usually made of Al_2O_3 , SiC, or garnet of the desired size at a predefined load. During the test, the pin sample is abraded constantly by the sliding within the abrasive paper. The wear is believed to simulate severe abrasive wear that can occur, for example, during rolling or slipping of tires against pavement or other abrasive floors. Parameters as abrasive material and size, pin specimen load and speed, path length and drum rotary speed can be varied in this test. The wear rate is typically estimated by measuring the mass loss of the pin specimen. The measurement of friction is not common in these testers.

Dry Sand Rubber Wheel Test

Severe three-body abrasion wear resistance of metals, ceramics, polymers and PMCs is widely evaluated by the dry sand rubber wheel test. Usually, a flat and robust block specimen is positioned vertically and loaded against the rim of a rotating rubber wheel while sand or other abrasive particles are fed into the gap between the rubber and specimen interface. The abrasive particles act as

the third-body abrader in the contact. The rubber helps the particles to slide against the block specimen consistently. This test is also known as low stress scratching abrasion test. Rolling and slipping of tires in the presence of sand or other abrasive particles can be replicated and evaluated with this test. Different loads, abrasive particles types and sizes, wheel speed and environmental conditions can be tested. The ASTM G65 and ISO 28080 are the typical standard methods based on the dry sand rubber wheel test. In general, they are focused on determining the wear rate and resistance of materials while friction measurement is not considered.

To end up this section, it is noteworthy that in the case of lubricated tests for PMCs, additional compatibility tests should be carried out since it is well known that certain polymers, depending on their polarities, may be incompatible with different solvents or lubricants (Farfan-Cabrera *et al.*, 2019). Incompatibility promotes accelerated degradation of the polymer in the solvent (i.e., automotive lubricants and combustibles) producing dissolution, swelling and/or hardening and loss of resilience (Farfan-Cabrera *et al.*, 2017a, 2018).

Automotive lubrication systems comprising PMCs components require good compatibility with lubricants to avoid failures due to degradation by incompatibility. Thus, novel developed PMCs should be compatible with most of the common lubricants used for the specific tribological application. Currently, there are not established standard tests for determining compatibility of polymer matrix composites with lubricants in different environmental conditions, but some standard tests for polymers compatibility, namely, ASTM-D471, ASTM-D7216, ASTM-D4289, ASTM D543, ISO 6072, ISO 175, etc., can be used. Basically, the procedures consist on conducting immersion tests of the polymers in the chemical fluid aimed under specific conditions, and then, measuring changes of their physical properties after a precise immersion period. The typical measured properties are mass, volume, hardness, tensile and tear strength, elongation, breaking resistance, burst strength, etc. The compatibility level is stated depending on the changes occurred after immersion.

Prospective Developments and Challenges

Automotive industry will continue demanding high-performance materials, including tribological PMCs. They should be able to sustain higher pressures, temperatures and velocities while being partially or totally eco-friendly. The emerging area of polymer nanocomposites offers expectative for achieving significant advances. The main advantage of nanocomposites over traditional PMCs is the ability of the former to improve both strength and toughness properties simultaneously and isotropically (Briscoe and Sinha, 2008). Considering that research and development of tribology of nanocomposites and hybrid composites is still scarce, but growing, many innovations in the automotive technology, even in new high-performance hardware, namely, micro- and nano-electro-mechanical systems (MEMS and NEMS), for electric vehicles will appear in the coming years (Friedrich, 2013; Farfan-Cabrera, 2019). Finally, the tribological application of PMCs is expected to grow as the usage of polymers expands to newer applications in vehicles. Since polymers do not always follow the rule of better strength and hardness for better wear resistance and desired COF, there will be always a need for fine-tuning tribological performances of the material without seriously compromising the bulk strength. Thus, a healthy rise in the research area of tribological PMCs is expected (Briscoe and Sinha, 2008).

Introduction

Only 0.8% of the earth's total water is clean water, which is a vital element for survival of all living things (Nasir *et al.*, 2019). Nowadays, with rapid industries development and increasingly growing world population, the global water shortage problem is becoming more and more serious. Currently, 2 billion people in the world do not have access to clean water, that may reach 4.6 billion by 2080 (Huang *et al.*, 2014). In many developing countries, almost 90% of contaminated water is discharged into environment directly without any treatment. Major sources of water pollution include municipal and industrial wastewater as well as agricultural activities (Nasir *et al.*, 2019). Consumption of contaminated water threatens human health and causes various diseases such as cancer, wounds, skin inflammations, diarrhea, fever and chills, headache and abdominal pain and loss of appetite (Dongre *et al.*, 2019). Therefore, providing clean water from limited water resources and removing contaminants from water/wastewater are very important. Among water pollutants, heavy metal ions and dyes are the most harmful (Qu *et al.*, 2012; Yang *et al.*, 2018; Teow and Mohammad, 2019).

Wastewater from many industries including battery manufacturing, chemical manufacturing, metallurgical, tannery and mining industries, etc., contains one or more toxic metal ions. Heavy metal ions as non-biodegradable compounds can be accumulated in living organisms easily and cause serious illnesses, such as cancer, damage to the nervous system, kidney failure and increasing blood and respiratory pressure. In addition, entry of toxic metal ions into food chain is possible through waste discharge into water bodies. Therefore, removing these metal ions from the wastewaters before discharging into environment is necessary (Rao *et al.*, 2007; García-Díaz *et al.*, 2018; Vuković *et al.*, 2010; Bystrzejewski and Pyrzyńska 2011; Tofighy and Mohammadi, 2011; Tofighy and Mohammadi, 2015).

Dyes as organic compounds with non-biodegradable and polluting nature are used in many industries including leather, paper, textile and plastic. About 750,000 tons of dye wastewaters are produced annually, worldwide. More than 10,000 dyes are available commercially which most of them have complex structures and are stable. Long-term exposure to dyes causes serious health problems including increased heart rate, shock, vomiting, eye burns, mental confusion, jaundice, cyanosis, limb paralysis, and tissue necrosis. Therefore, to reduce the dye impact on the organisms, dyes removal from wastewater before releasing into the environment is of great interest (Tan *et al.*, 2007, 2008; Choi *et al.*, 2018; Gherbia *et al.*, 2019; Sahu *et al.*, 2019; Etim, 2019; Tofighy and Mohammadi, 2014; Liu *et al.*, 2018; Franciski *et al.*, 2018; Lonappan *et al.*, 2016; Gong *et al.*, 2005).

Among the various methods of water/wastewater treatment including ion exchange, evaporation and condensation, chemical precipitation, electrodialysis, ultrafiltration, reverse osmosis, and adsorption, the last is one of the most promising methods from the view point of productivity, simplicity and economy (Tofighy and Mohammadi, 2011). Efficiency of the adsorption process depends on the adsorbent properties, directly (Tofighy and Mohammadi, 2015). Traditional adsorbents such as activated carbon (AC), coal, fly ash, zeolites, resins and etc. have limited practical applications due to their recovery problems and low adsorption capacity. Therefore, many efforts are being made to achieve new and high-yield adsorbents with high absorption capacity (Tofighy and Mohammadi, 2014). Recently, polymer matrix composites materials have shown significant potential as new adsorbents for water/wastewater treatment applications (Berber, 2020).

New materials are the basis of new technologies. In the twentieth century, with the advent of high-performance composites, as suitable alternative to traditional materials, much progress has been made in all scientific areas. Composite materials as a combination of two or more materials are composed of two main parts: matrix materials as continuous phase and filler materials as dispersed phase. The continuous phase can be metallic, ceramic or polymeric materials. The dispersed phase can be tubular, fiber, sheet and particle-like structure materials. The properties of composite materials directly depend on the properties of the continuous phase, the dispersed phase and their interfaces (Wang *et al.*, 2011).

Polymer matrix composite materials (PMCs) are defined as combination of inorganic or organic materials with polymers that provide new materials with new properties such as high mechanical strength and hardness, low density and optimal, chemical and thermal stability depending on the type of use. PMCs with high absorption capacity of dyes, heavy metal ions and other water pollutants can be used as effective adsorbents in water/wastewater treatment applications (Dongre *et al.*, 2019; Berber, 2020; Pandey *et al.*, 2017).

Carbon nanomaterials specially carbon nanotubes (CNTs) and graphene family including graphene oxide (GO) and reduced graphene oxide (rGO) with unique physical and chemical properties have received the researchers and scientist's attention worldwide and have encouraged them to use these nanomaterials to fabricate new PMCs for water/wastewater treatment applications.

In this article, current progresses in polymer matrix composites materials as adsorbent for water/wastewater treatment applications will be reviewed.

Bibliometric Analysis

The main aspects related to the applications of the polymer matrix composites materials in water/wastewater treatment can be identified by bibliometric analysis. Fig. 1 illustrates the number of scholarly studies including books, book articles, journal articles,

Fig. 1 Scholarly studies in the field of applications of the polymer matrix composites materials in water/wastewater treatment.

conference proceeding articles, dissertations, etc., in this research field, over time. As can be clearly observed, the number of scholarly studies accomplished over the years of 1980–2015 have been significantly increased and then over the years of 2015–2020 decreased to some extent. Among all of the scholarly works, the journal articles have the highest share 91.3%. **Fig. 2** shows the top publishers by the number of scholarly works in this field. As can be observed, the Elsevier publisher have been published the greatest number of the scholarly works in this research field.

Fig. 3 shows the clusters network visualization of the keywords with the most frequent co-occurrence in the field of the applications of the polymer matrix composites materials in water/wastewater treatment. This chart was obtained by importing the data downloaded from the Scopus into the VOSviewer software (version 1.6.15) and provided valuable information about the scholarly studies conducted so far in this research field. Each circle represents a keyword. The bigger the circle, the bigger the occurrence. The co-occurrence relationship between the keywords is presented by curves. Moreover, the distance between two keywords indicates the relationship strength, i.e., the closer the keywords, they are the more related and vice versa. As shown in **Fig. 3**, the keywords are divided into three clusters with different colors:

- (1) Cluster 1 (in green) mainly includes the keywords related to the topic of applications of polymer matrix composites as adsorbent, such as “adsorption”, “adsorbent”, “kinetic models”, “diffusion”, “isotherms”, “Langmuir”, “heavy metal”, “metal ions”, “kinetics”, “chitosan”, “water purification”, “pH”, “dye” and “removal efficiencies”.
- (2) Cluster 2 (in red) mainly includes the keywords related to the topic of applications of polymer matrix composites as membrane, such as “membranes”, “polymeric membranes”, “nanocomposite membranes”, “membrane fabrication”, “interfacial polymerization”, “thin film”, “desalination”, “osmosis”, “forward osmosis”, “thin film composite membrane”, “hydrophilicity”, “surface property”, “microfiltration” and “polyvinylidene fluoride”.
- (3) Cluster 3 (in blue) mainly includes the keywords related to the topic of polymer matrix composites fabrication and their properties, such as “optical properties”, “tensile strength”, “silica”, “carbon”, “graphene”, “catalyst activity”, “fillers”, “mesoporous”, “surface area”, “morphology”, “chemical composition”, “turbidity”, “solubility” and “polyvinyl alcohol”.

These three clusters reveal the major research directions in the field of applications of the polymer matrix composites materials in water/wastewater treatment. It is obvious that the polymer matrix composites materials can be used as adsorbent and membrane materials. Application of the polymer matrix composites materials as membrane materials has been reviewed frequently by other authors (Nasir *et al.*, 2019; Zahid *et al.*, 2018; Grylewicz and Mozia, 2020).

Adsorption

The “adsorption” word was first introduced by Heinrich Kayser, a German physicist, in 1881. The transfer of atoms, ions or molecules from the gas or liquid phase to the solid structure is called adsorption. The solid on which adsorption occurs is called “adsorbent” and the substance being adsorbed is called “adsorbate”. Adsorption capacity is defined as the amount of volume or mass of adsorbate per unit of adsorbent mass. The adsorption process can be done in both chemical and physical forms. The

Fig. 2 The top publishers based on the number of accomplished scholarly studies in the field of applications of the polymer matrix composites materials in water/wastewater treatment. Reprinted from lens.org.

chemical adsorption (chemisorption) is done by chemical bonding (covalent bonding) between the adsorbent and the adsorbate. In physical adsorption (physisorption), the intermolecular forces between the adsorbate and the adsorbent are electrostatic or van der Waals interactions. Physical adsorption can be multilayer, but chemical adsorption is monolayer (Dąbrowski, 2001; Ruthven, 1984). The relationship between the equilibrium concentration of adsorbate (C_e) and the equilibrium adsorption capacity (q_e), at constant temperature, is described by adsorption isotherm models. There are numerous adsorption isotherm models including Langmuir, Freundlich, Redlich–Peterson, Sips and Liu isotherm models. Useful information about the adsorption mechanism, adsorbent/adsorbate interactions and surface properties can be achieved by the adsorption isotherm models parameters (Langmuir, 1918; Freundlich, 1906; Sips, 1948; Liu *et al.*, 2003; Redlich and Peterson, 1959; Tofighy and Mohammadi, 2010). Matching of the experimental data with the Langmuir and Freundlich isotherm models shows that adsorption is controlled by chemisorption (monolayer) and physisorption (multilayer), respectively. Also, valuable information about the adsorption process mechanism (physisorption or chemisorption) can be provided by adsorption kinetic studies by applying the adsorption kinetic models such as pseudo-first and second-order kinetic models and etc (Tofighy and Mohammadi, 2011; Lagergren, 1898; Blanchard *et al.*, 1984; Alencar *et al.*, 2012; Vaghetti *et al.*, 2009). Matching of the pseudo-first and pseudo-second order kinetic models with the experimental data shows that adsorption is controlled by physisorption and chemisorption, respectively (Senthilkumaar *et al.*, 2005; Oukil *et al.*, 2019; Tran *et al.*, 2016).

Composites

From the view point of materials science, human society has experienced the age of stone, bronze and iron. Composite materials as new materials were first introduced in the 1950s. Composite materials are composed of two or more components with different properties and different shapes. This combination not only preserves the properties of each component but also reveals new properties that are not available by any of the composite components (Petre *et al.*, 2015). Composite components are microscopically impermeable and have a distinct interface. Composites should have much better performance than each component. The development of composite materials as a multiphase system should be done using material design. Composite materials are composed of two main parts: matrix materials as continuous phase and filler materials as dispersed phase. The continuous phase can be made of metallic, ceramic or polymeric materials. Composites are classified based on the type of matrix materials including ceramic matrix composites (CMCs), metal matrix composites (MMCs) and polymer matrix composites (PMCs) as shown in Fig. 4. The dispersed phase can be tubular, fiber, sheet and particle-like structure materials including carbon nanomaterials, zeolites,

Polymer Matrix Composites (PMCs)

Polymer-organic composites adsorbents

Polyacrylonitrile (PAN) is considered as one of the most important precursors for polymer-organic composites fabrication. PAN-based PMCs are distinguished by their hardness, compatibility with polar substances and chemical stability and can be

Fig. 4 Classification of composite materials.

functionalized easily to fabricate novel adsorbents for different applications including metal chelation and water/wastewater treatment (El-Aassar *et al.*, 2016). Poly(acrylonitrile-co-styrene), as an important copolymer of acrylonitrile and styrene, with superior properties including excellent chemical and heat resistance, high rigidity and superior transparency can be used as an effective adsorbent material for removal of harmful pollutants from wastewater (de Santa Maria *et al.*, 2001). Elkady *et al.* reported synthesis of a copolymer of acrylonitrile and styrene (poly(AN-co-ST)) via solution polymerization process. They fabricated nanofiber adsorbent using the synthesized poly(AN-co-ST) via electrospinning method, and to increase the dye adsorption capacity of the fabricated adsorbent, the nanofibers surface was functionalized by carboxylic acid groups via a simple chemical modification. It was found that after the nanofiber surface functionalization, the adsorption capacity of the basic violet dye reached 67.11 mg/g (in less than 30 min). Also, it was found that the both Langmuir and Temkin isotherm models well describe the dye adsorption behavior at equilibrium and the main decolorization rate controlling is the intraparticle diffusion kinetic model (Elkady *et al.*, 2016).

With combination of polymers and compounds containing different functional groups including carboxyl and amine, effective adsorbents can be fabricated for dyes removal from wastewater. PAN as a common and inexpensive commercial polymer with desirable thermal and chemical properties and good solubility in organic solvents is a desirable polymer for fabrication of composite nanofibers adsorbents via electrospinning technique for wastewater treatment applications (Deng *et al.*, 2003).

Almasian *et al.* incorporated diethylenetriamine (DETA) into PAN using electrospinning technique to fabricate DETA/PAN composite nanofibers with high dye adsorption capacity. Using alkali treatment, DETA was fixed to the polymer to hinder DETA releasing. It was found that DETA incorporation into PAN affects nanofibers morphology, directly. Also, it was found that the amount of adsorbed dye is influenced by the ratio of DETA added to the composite. Adsorption behavior of the fabricated DETA/PAN composite adsorbent matched well with the Langmuir isotherm model for C.I direct red 80 (DR80) dye removal (Almasian *et al.*, 2015).

Cyclodextrin-based composites with unique chemical and physical properties and porous structure have been extensively regarded by researchers for removing dyes from wastewater. The used of cyclodextrin as a practical adsorbent was limited due to its water solubility. To improve its insolubility, modification of cyclodextrin by self-crosslinking or immobilization through its abundant hydroxyl groups is an effective way (Liu *et al.*, 2020). Chen *et al.* reported fabrication of an eco-friendly composite adsorbent for removal of cationic dyes including crystal violet (CV), malachite green (MG), methylene blue (MB) and copper ion (Cu^{2+}) by crosslinking cyclodextrin polymer with polydopamine (CD-CA/PDA) that combines the advantages of both polydopamine and cyclodextrin. The fabrication steps of the CD-CA/PDA composite adsorbent are presented in Fig. 5. It was found that the fabricated CD-CA/PDA composite adsorbent with abundant carboxyl and catechol functional groups exhibits excellent adsorption properties. Also, it was found that the adsorption capacity of the fabricated CD-CA/PDA composite adsorbent is correlated to its functional groups and structural characteristics. The pseudo-second-order model matched well with the adsorption kinetic results demonstrating that adsorption is controlled by chemical adsorption. The fabricated CD-CA/PDA composite adsorbent exhibited great recyclability (at least 5 times) (Chen *et al.*, 2020).

Zhang *et al.* reported fabrication of β -Cyclodextrin (β -CD) immobilized with starch by introducing β -cyclodextrin as host functional molecule onto starch in presence of citric acid. The fabricated composite was used as a natural polymeric composite adsorbent for three cationic dyes (MB, basic fuchsin and methyl purple) removal from wastewater. It was found that the fabricated β -cyclodextrin-starch composite exhibits higher dye adsorption capacity than each of starch and β -cyclodextrin, separately that can be attributed to the functional groups of the starch- β -cyclodextrin composite including NH_2 , OH and COOH and the obtained irregular surface that plays significant role in the dye removal. It was found that the adsorption behavior of the fabricated composite adsorbent matches well with the both Langmuir and Freundlich isotherm models (Zhang *et al.*, 2019).

Cellulose is a biodegradable, linear and most abundant polysaccharide of β -D-glucopyranose units that are linked by β -1,4-glycosidic linkages. Vinyl monomers grafting on the hydroxyl (-OH) groups of cellulose is an effective way to enhance its physicochemical, hydrophilic/hydrophobic, swelling, thermal and mass-transfer properties (Kumar *et al.*, 2017; Hokkanen *et al.*, 2016).

Fig. 5 The fabrication steps of the CD-CA/PDA composite adsorbent. Reproduced from Chen, H., Zhou, Y., Wang, J., Lu, J., Zhou, Y., 2020. Polydopamine modified cyclodextrin polymer as efficient adsorbent for removing cationic dyes and Cu_2 . *Journal of Hazardous Materials* 389, 121897.

Yue *et al.* reported fabrication of an efficient composite adsorbent for dyes removal from wastewater by grafting beta-cyclodextrin (β -CD) and amino-terminated hyperbranched polymer (NH_2 -HBP) onto cotton fibers as a kind of renewable, eco-friendly and abundant cellulose fiber in nature. The fabricated composite adsorbent exhibited remarkable adsorption properties for dyes (Congo red (CR) and MB) removal that can be related to its functional groups. It was found that pH value has great effect on the adsorption capacity of dyes (Yue *et al.*, 2017).

Kumar *et al.* reported fabrication of a highly efficient co-polymer composite adsorbent for dye removal from wastewater by functionalization of cellulose extracted from agricultural wastes through free radical grafting with a binary vinyl monomer mixture of acrylic acid and 2-acrylamido – 2- methylpropane sulfonic acid in the presence of cross-linker ($\text{N,N}'$ -methylene bisacrylamide). The adsorption behavior of the fabricated copolymer (Cell-g-AASO3H-co-AAc) was studied for removal of MG, CV, CR dyes and Cu(II) and Ni(II) metal ions from aqueous solutions. It was found that the experimental adsorption data are well fitted with the pseudo-second-order kinetic model and the Langmuir isotherm model. SEM images of the neat cellulose and the fabricated Cell-g-AASO3H-co-AAc composite adsorbents are shown in Fig. 6. (Kumar *et al.*, 2018).

Zhu *et al.* reported functionalization of cellulose with hyper-branched polyethylenimine (HPEI) as an amino-rich cationic polyelectrolyte to fabricate HPEI-CE polymer composite adsorbent for anionic (CR) and cationic (BY28) dyes removal from aqueous solution. The aldehyde groups on the surface of chemically oxidized cellulose are covalently linked with NH_2 groups of HPEI. It was found that the adsorption behavior of the fabricated HPEI-CE composite adsorbent matches well with the Langmuir isotherm model with maximum adsorption capacity of 1860 mg/g for BY28 and 2100 mg/g for CR, respectively. It was found that the hyper-branched structure of the polymer composite adsorbent improves the interparticle dye molecules diffusion into the composite (Zhu *et al.*, 2016).

In order to rise the adsorption capacity of polymers, copolymerization process can be performed in which a new polymer with improved properties is obtained by combining one or more polymers with each other (Abdullah *et al.*, 2019).

Hosseinzadeh *et al.* reported fabrication of a composite adsorbent by modification of poly(styrene-maleicanhydride) copolymer (SMA) with 3-(4-hydroxy phenyl) cyclopropane-1,1,2,2-tetramethyleneamine (HPCA) and subsequently reacting the product (SMA-HPCA) with 1,2-diaminoethane (DAE) for preparation of tridimensional chelating resin (CSMA-HPCA) as a new copolymer with multiprimary amines cyclopropane functionalities in the pendant group for heavy metal ions (Cu(II) , Pb(II) , Zn(II)) removal from aqueous solution. It was found that the adsorption behavior of the synthesized CSMA-HPCA composite adsorbent follows the pseudo-second order kinetic and the Langmuir isotherm models (Hosseinzadeh, 2018).

Chen *et al.* reported fabrication of a novel polyamine-type starch/glycidyl methacrylate copolymer by copolymerization of corn starch and glycidyl methacrylate (GMA) and a subsequent amination reaction between epoxy groups of GMA and amino groups (NH_2) of diethylenetriamine. The fabricated composite adsorbent was used for heavy metal ions (Pb(II) , Cu(II) , Cr(III) and Cd(II)) removal from wastewater. The maximum adsorption capacities of the fabricated composite adsorbent for Cu(II) , Pb(II) , Cd(II) and Cr(III) were achieved up to 2.33, 1.25, 0.83 and 0.56 mmol g^{-1} , respectively. The fabricated adsorbent exhibited high adsorption capacity and excellent reusability (high adsorption capacity after 10 cycles of adsorption/desorption tests) (Chen *et al.*, 2018).

Yu *et al.* covalently linked EDTA-modified chitosan (CS-EDTA), β -cyclodextrin (β -CD) and pentafluoropyridine together to fabricate porous organic polymeric composite adsorbents for efficient heavy metal ions (Ni(II) , Pb(II) , Hg(II) , Co(II) , Cu(II) , Cr(II)) removal from wastewater. The fabricated composite adsorbents exhibited high adsorption capacity and good reusability (high adsorption capacity after 5 cycles of adsorption-desorption experiments) (Yu *et al.*, 2018).

Fig. 6 SEM images of the neat cellulose and the fabricated Cell-g-AAS03H-co-AAC composite adsorbents. Reproduced from Kumar, R., Sharma, R.K., Singh, A.P., 2018. Removal of organic dyes and metal ions by cross-linked graft copolymers of cellulose obtained from the agricultural residue. *Journal of Environmental Chemical Engineering* 6, 6037–6048.

Among the polymer-based adsorbents, conducting polymer-based adsorbents like polyethylenimine (PEI), polypyrrole (Ppy), polyaniline (PANI) and their composites have received great attention as appropriate adsorbents for various heavy metal ions removal due to their low cost, ease of synthesis and regeneration and high chemical and mechanical stability (Mahmud *et al.*, 2006). Also, their highly porous structure and ion exchange capacities have also attracted researchers. The conducting polymer-based composites can be used effectively for different heavy metal ions removal from wastewater (Mahmud *et al.*, 2016). Polypyrrole as a conducting polymer containing positively charged nitrogen atoms with appropriate properties can be used to fabricate the polypyrrole based composites for heavy metal ions removal due to its biocompatibility properties and simple fabrication process. (Mahmud *et al.*, 2016; Yao *et al.*, 2009) Mahmud *et al.* published a review paper about heavy metal ions removal from water/wastewater by the polypyrrole-based composite adsorbents (Mahmud *et al.*, 2016).

Understanding the interactions between functional groups of polymer composites with various pollutants is very important because it will conduct the future studies to achieve the optimum removal efficiency of the target contaminants.

Polymer-inorganic composite adsorbents

Among a wide variety of known inorganic nanomaterials, carbon nanomaterials have recently attracted tremendous attention. Among carbon nanomaterials, carbon nanotubes (CNTs) and graphene oxide (GO) with unique properties could improve adsorption capacity of the polymer matrix composites, significantly.

CNTs-based PMCs

CNTs as an important member of the carbon nanomaterials family, have unique properties such as high specific surface area, low mass density, high thermal stability and mechanical stiffness, frictionless surface, high flexibility, ability to form π - π interactions with aromatic compounds, and high aspect ratio (length to diameter ratio more than 1000) and can be easily surface modified. Among the several nanomaterials based adsorbents, CNTs with greater available specific surface area, hollow structure, hydrophobic nature, higher porosity, ease of functionalization and well-developed micro and meso-pores have been recognized as excellent adsorbent for removal of various pollutants. CNTs as cylindrical macromolecules composed of sp^2 hybridized carbon atoms are divided into three categories of single-walled (SWCNTs), double-walled (DWCNTs) and multi-walled carbon nanotubes (MWCNTs) as shown in Fig. 7 (Tofighy and Mohammadi, 2011; Tofighy and Mohammadi, 2019; Mashkooor and Nasar, 2020; Tofighy and Mohammadi, 2020; Tofighy and Mohammadi, 2012).

Chemical or physical functionalization of CNTs with polymers is regarded as one of the most effective methods to increase hydrophilicity and water solubility as well as CNTs adsorption properties. The CNTs-based composites have received increasing attention for adsorptive removal of contaminants from wastewater. The CNTs-based composites with enhanced adsorption capability can be fabricated via surface functionalization of CNTs with polymers as an effective approach.

Bankole *et al.* functionalized CNTs with polyhydroxybutyrate to fabricate efficient composite adsorbent (PHB-CNTs) for heavy metal ions (As, Pb, Cr, Cd, Ni, Cu, Fe, and Zn) removal from wastewater. It was found that hydrophilic characteristics and adsorption capacities of CNTs are enhanced after functionalization with the polymer, significantly. It was found that the adsorption behavior of the synthesized adsorbent fits well with the Temkin isotherm and the pseudo-second-order kinetic models (Bankole *et al.*, 2019).

Dendrimers with abundant surface functional groups including carboxyl, amine and hydroxyl can lead to enhance the heavy metal ions adsorption capacity of CNTs. Hayati *et al.* coated CNTs with polyamidoamine dendrimer (PAMAM) and the fabricated

Fig. 7 Scheme of (a) SWCNT, (b) DWCNT and (c) MWCNT.

composite was used as adsorbent for heavy metal ions removal. The fabricated composite exhibited significant adsorption capacities of As(III), Co(II), and Zn(II) ions as 432, 494, and 470 mg/g, respectively. A schematic of the fabrication process for the PAMAM-CNTs composite adsorbent is shown in [Fig. 8](#) ([Hayati et al., 2018](#)).

Hydrogels can be widely used as effective adsorbent in water treatment application due to their low cost, facile preparation and high adsorption capacity. Yue *et al.* reported fabrication of polyacrylamide (PAAm)-sodium alginate (SA) interpenetrating polymer network-structured hydrogels through in situ polymerization method. Then, they incorporated CNTs into the PAAm-SA matrix via hydrogen bonding. The fabricated hydrogel with macroporous structure exhibited high water content ($\approx 83\%$) and low density ($\approx 1.4 \text{ g/cm}^3$). It was found that CNTs addition improves elasticity, mechanical strength and adsorption capacity of the fabricated hydrogel. Also, it was found that compared to the neat hydrogel, adsorption capacity of the fabricated CNTs-based hydrogel increases 1.28 times ([Yue et al., 2019](#)).

Kumar *et al.* reported fabrication of MWCNTs-polyaniline (Pani) composite via oxidation polymerization methodology. Then, the fabricated composite was doped with hydrophilic groups of para-toluene-sulfonic acid. These additional functional groups enhanced water dispersion and adsorption capacity of the prepared composite. The as-synthesized pTSA-Pani@CNT composite was used as adsorbent for hexavalent chromium (Cr(VI)) removal from aqueous solution. It was found that the as-synthesized pTSA-Pani@CNT composite exhibits higher Cr(VI) adsorption capacity than the pTSA-CNT and pTSA-Pani composites. A schematic illustration representing fabrication of the pTSA-Pani@CNT composite adsorbent for adsorptive removal of Cr(VI) is shown in [Fig. 9](#) ([Kumar et al., 2019](#)).

Xie *et al.* reported fabrication of poly (sodium-p-styrene sulfonate) modified CNTs (PDA-PSPSH-CNT) composite adsorbent for cationic dye (MB) removal from aqueous solution. It was found that the adsorption capacity of MB is inversely proportional to temperature and directly proportional to contact time. It was found that the fabricated PDA-PSPSH-CNT composite adsorbent with the maximum adsorption capacity of MB as 160 mg/g, exhibits excellent adsorptive property ([Xie et al., 2015](#)).

Wu *et al.* reported fabrication of O-MWCNTs/PANI composite adsorbent based on MWCNTs encapsulation by polyaniline (PANI) via in situ polymerization method for adsorptive removal of alizarin yellow dye from wastewater (with maximum adsorption capacity of 884.80 mg/g). It was found that the adsorption behavior of the fabricated O-MWCNTs/PANI composite adsorbent fits well by the Langmuir isotherm and the pseudo-second-order kinetic models. Also, it was found that the fabricated O-MWCNTs/PANI composite adsorbent exhibits higher adsorption capacity than the pristine PANI or MWCNTs ([Wu et al., 2018](#)).

Mallakpour *et al.* recycled poly(ethylene terephthalate) (PET) bottle waste and fabricated PET/carboxyl-functionalized MWCNTs for adsorptive removal of Cd (II) metal ions from aqueous solution. It was found that the fabricated composite exhibits high adsorption capacity of Cd (II) metal ions, high electrical conductivity as well as good flame retardancy ([Mallakpour and Behranvand, 2017](#)).

Zarghami *et al.* reported fabrication of polyvinyl alcohol/chitosan composite adsorbent containing acid-functionalized CNTs (PVA/CS-CNTs) via solution casting method for adsorption of lead and zinc metal ions from aqueous solutions. It was found out that the adsorption behaviors of zinc and lead metal ions using the fabricated CS/PVA-CNTs composite adsorbent match well with the pseudo-first-order kinetic model and the Freundlich isotherm model ([Zarghami et al., 2015](#)).

GO-based PMCs

Graphene as a two-dimensional monolayer of sp^2 -hybridized carbon atoms is the basic building block of all other graphitic carbon allotropes. GO as an important member of graphene family with many attractive properties such as hydrophilic nature, superior mechanical stability, good miscibility with polymers, high flexibility and its negatively charged surface can be incorporated into polymer matrices to fabricate composite adsorbent. GO as a well-known inorganic nanomaterial with abundant oxygen-containing functional groups on its basal plane and edges (hydroxyl (-OH) and epoxy (C-O-C) groups in the basal plane and carboxylic acid (-COOH) groups at the edges) displays an extensive prospect in water and wastewater treatment field. These functional group can provide high density of negatively charge as suitable sites for removal of adsorbates with positively charge including heavy metal ions ([Mishra and Ramaprabhu, 2011](#); [Ren et al., 2013](#)) and cationic dyes ([Ramesha et al., 2011](#); [Yang et al., 2011](#)). Also, existence of the oxygen-containing functional groups on the GO structure facilitates chemical modification of GO to enhance its adsorption capacity.

Fig. 8 A schematic of the PAMAM-CNTs composite adsorbent fabrication process. Reproduced from Hayati, B., Maleki, A., Najafi, F., *et al.*, 2018. Heavy metal adsorption using PAMAM/CNT nanocomposite from aqueous solution in batch and continuous fixed bed systems. *Chemical Engineering Journal* 346, 258–270.

Beside GO, reduced GO (rGO) can also be used as adsorbent for environmental applications (Ramesha *et al.*, 2011; Tiwari *et al.*, 2013; Pan *et al.*, 2013). The rGO can be prepared through chemical or thermal reduction of GO to decrease its oxygen content (partial deoxygenation) (Bianco *et al.*, 2013). A schematic illustration of graphene, GO and rGO is shown in Fig. 10.

Chandra *et al.* reported fabrication of polypyrrole–reduced graphene oxide (PPy-rGO) composite adsorbent via a chemical route for adsorptive removal of Hg(II) from aqueous solution. It was observed that the pyrrole polymerized along graphene

Fig. 9 A schematic illustration of the pTSA-Pani@CNT composite adsorbent fabrication for adsorptive removal of Cr(VI). Reproduced from Kumar, R., Ansari, M.O., Alshahrie, A., *et al.*, 2019. Adsorption modeling and mechanistic insight of hazardous chromium on para toluene sulfonic acid immobilized-polyaniline@ CNTs nanocomposites. *Journal of Saudi Chemical Society* 23, 188–197.

Fig. 10 Schemes of (a) Graphene, (b) GO and (c) rGO.

nanosheets exhibits an enhanced surface area. The fabricated PPy-rGO composite as a stable and environmentally friendly adsorbent exhibits excellent adsorption capacity for Hg(II) as high as 980 mg/g (Chandra and Kim, 2011).

Li *et al.* reported fabrication of polyaniline-reduced graphene oxide (PANI-rGO) composite adsorbent through aniline polymerization in the presence of GO and reduction by hydrazine hydrate for adsorptive removal of Hg(II) from aqueous solution. As reported, compared to PANI, the maximum adsorption capacity of the fabricated PANI-rGO composite adsorbent for Hg(II) is enhanced from 515 to 1000 mg/g that is due to the presence of rGO resulting in 7 times enhancement in adsorption sites and specific surface area. Also, nitrogen-containing functional groups in polyaniline structure act as adsorption sites for heavy metal ions removal (Li *et al.*, 2013).

Fig. 11 A schematic illustration for fabrication procedure of the PDDA/GO composite adsorbent. Reproduced from Wang, X., Liu, Z., Ye, X., *et al.*, 2014. A facile one-step approach to functionalized graphene oxide-based hydrogels used as effective adsorbents toward anionic dyes. *Applied Surface Science* 308, 82–90.

Fig. 12 A synthesis illustration for fabrication procedure of the PAM/rGO composite adsorbent. Reproduced from Yang, Y., Xie, Y., Pang, L., *et al.*, 2013. Preparation of reduced graphene oxide/poly (acrylamide) nanocomposite and its adsorption of Pb (II) and methylene blue. *Langmuir* 29, 10727–10736.

Fan *et al.* reported fabrication of graphene oxide-sodium alginate-polyacrylamide (GO-SA-PAM) composite hydrogel adsorbent with excellent mechanical property through free-radical polymerization of SA and acrylamide (AAM) in the presence of GO in an aqueous system followed by crosslinking with Ca^{2+} . GO nanosheets were used as reinforcing filler and due to hydrogen bonding between the O–H bond of GO nanosheets and the N–H bond of PAM, mechanical properties of the fabricated composite improved, significantly. It was

Fig. 13 A schematic illustration for fabrication procedure of the GO/P(AA-co-AM) composite absorbent. Reproduced from Huang, Y., Zeng, M., Ren, J., *et al.*, 2012. Preparation and swelling properties of graphene oxide/poly (acrylic acid-co-acrylamide) super-absorbent hydrogel nanocomposites. *Colloids and Surfaces A: Physicochemical and Engineering Aspects* 401, 97–106.

found that the fabricated GO-SA-PAM composite adsorbent exhibits high adsorption capacities for numerous anionic and cationic dyes. Also, after the GO incorporation into the composite adsorbent, the dyes adsorption capacities improve, significantly (Fan *et al.*, 2013).

Wang *et al.* reported fabrication of poly(diallyldimethylammonium chloride)-graphene oxide (PDDA-GO) hydrogel composite adsorbent through self-assembling method for adsorption of anionic dyes from aqueous solution. It was found that the fabricated PDDA/GO composite adsorbent exhibits high removal efficiency for both trypan blue (TB) and ponceau S (PS) anionic dyes due to the strong anion-cation and π - π interactions. Also, the adsorption behavior of the fabricated PDDA/GO composite adsorbent fits well with the pseudo-second-order kinetic model. A schematic illustration for fabrication procedure of the PDDA/GO composite adsorbent is shown in Fig. 11 (Wang *et al.*, 2014).

Yang *et al.* reported fabrication of poly(acrylamide)/rGO composite adsorbent (PAM/rGO) by synthesis of poly(acrylamide) polymer brushes on the rGO nanosheets through in situ free-radical polymerization for adsorptive removal of Pb(II) metal ions and MB from aqueous solutions. It was found that the adsorption behavior of the fabricated PAM/rGO composite adsorbent well fits with the Langmuir isotherm model and the pseudo-second-order model. The fabricated PAM/rGO composite adsorbent exhibits adsorption capacities as high as 1530 and 1000 mg/g for MB and Pb(II), respectively. A schematic illustration for fabrication procedure of the PAM/rGO composite adsorbent is shown in Fig. 12 (Yang *et al.*, 2013).

Huang *et al.* reported fabrication of GO/poly(acrylic acid-co-acrylamide) composite absorbent through in situ radical polymerization. It was found that owing to the possible hydrogen and covalent bonds between polymer chains and GO, GO can be dispersed well in the polymer matrix and this increases the intermolecular interactions between the components, effectively. A schematic illustration for fabrication procedure of the GO/P(AA-co-AM) composite absorbent is shown in Fig. 13 (Huang *et al.*, 2012).

Cheng *et al.* reported fabrication of GO/poly(acrylic acid) composite adsorbent (GO/PAA) for adsorptive removal of MB from aqueous solution. It was found that the fabricated PAA/GO composite has an interconnected three-dimensional porous network, which enhances its adsorption capacity by allowing the adsorbate (MB) molecules to diffuse easily into its porous structure. The highest MB adsorption capacity of the prepared PAA/GO composite adsorbent reaches as high as 1600 mg/g. It was found that the adsorption behavior of the prepared PAA/GO composite adsorbent matches well with the Langmuir isotherm model and the pseudo-second-order kinetic model and the adsorption process is controlled by the intraparticle diffusion model (Cheng *et al.*, 2014).

Conclusions

Polymer matrix composites (PMCs) as a combination of polymers with other organic or inorganic materials with high adsorption capacity of heavy metal ions, dyes and other water pollutants can be used in water/wastewater treatment applications as adsorbent, effectively. Carbon nanomaterials as inorganic nanofillers with unique chemical and physical properties can improve the PMCs performance in terms of adsorption capacity and mechanical, chemical and thermal resistance. Although the carbon nanomaterials

based-PMCs adsorbents are promising in laboratory studies, in order to commercialize the carbon nanomaterials-PMCs adsorbents for practical applications in very near future, a lot of research work should be performed. The future commercialization and development of the carbon nanomaterials based-PMCs adsorbents face a variety of challenges including potential environmental and human risk, cost-effectiveness and technical hurdles. Therefore, prior to the application of the carbon nanomaterials specially CNTs in water/wastewater treatment, deep toxic studies are crucially needed. Also, further efforts to decrease the carbon nanomaterials cost make brighter future for the carbon nanomaterials based-PMCs adsorbents in the water/wastewater treatment sector.

Introduction

A huge amount of wastewater contaminants with various toxic pollutants (ex. heavy metals and metalloids, pesticides, phenols, polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and polybrominated diphenyl ethers) are annually released into the environment as a result of rapid industrialization and harmful anthropogenic activities. The disposal of such effluents in the environment without any treatment is a serious threat to the plant, animals, and human health along with the waste of valuable resources. Some of the commonly used techniques for the treatment of industrial effluents are precipitation, adsorption, membrane filtration, ion exchange, ion flotation, reverse osmosis, complexation, photo- and electro-catalysis, and electrodialysis (Fu and Wang, 2011; Barakat, 2011; Zhu *et al.*, 2016; Szczepanik, 2017). Despite the widespread practical application of these methods, the complex operation, high capital and energy costs, low selectivity, slow separation kinetics, sludge formation, unproven performance in large-scale implementation, inefficient treatment of wastes with low contaminant concentration or complex structure contaminant, and the risk of secondary pollution limit their application in large-scales. Among the aforementioned methods, adsorption is one of the most efficient technologies for the wastewater purification (Raval *et al.*, 2016; Singh *et al.*, 2018). Some of the common types of organic and inorganic adsorbents previously used in wastewater treatments are natural and activated zeolites (Singh *et al.*, 2018; Bosso and Enzweiler, 2002; Inglezakis *et al.*, 2003; Syafalni *et al.*, 2014), natural and modified clay minerals (Fan *et al.*, 2009; Rusmin *et al.*, 2015; Olu-Owolabi *et al.*, 2017; Mukhopadhyay *et al.*, 2017; Kumararaja *et al.*, 2018; Yadav *et al.*, 2019; Han *et al.*, 2019), activated carbons (Singh *et al.*, 2018; Mirmohseni *et al.*, 2012; Nethaji *et al.*, 2013; Ahmed, 2017), biochar (Mohan *et al.*, 2014; Xie *et al.*, 2015; Shaheen *et al.*, 2019; Palansooriya *et al.*, 2020; Premarathna *et al.*, 2019), agricultural waste (Anastopoulos and Kyzas, 2014; Bhatnagar *et al.*, 2015; Shakoar *et al.*, 2018; Ahmad and Danish, 2018), industrial waste and sludge materials (Bhatnagar and Sillanpää, 2010; Zhao *et al.*, 2016; Anastopoulos *et al.*, 2017), and polymeric resins (Singh *et al.*, 2018; Rivas and Munoz, 2009; Gandhi *et al.*, 2010). A proper selection of adsorbents depends on the adsorption efficiency, benefit to cost ratio, and the specificity of a particular toxic agent. Among the mentioned adsorbents, natural clay minerals are intensively used due to their easy availability and cost-effectivity (Mukhopadhyay *et al.*, 2017), however, the low surface area, low potential of removing micro-pollutants, and lack of standard protocols of regeneration and recovery in aqueous systems, limit their usage (Unuabonah *et al.*, 2018; Sarkar *et al.*, 2019; Unuabonah and Taubert, 2014; Bhattacharyya and Gupta, 2008). Polymeric resin adsorbents have the potential of overcoming the drawbacks of clay minerals; however, they possess some negative characteristics including pH dependency, high cost, poor water wettability, and particle size sensitivity, which limit their widespread applications (Unuabonah and Taubert, 2014). Considering the advantages and disadvantages of the nano and polymeric adsorbents, researchers have paid attention to the development of polymer nanocomposites (PNCs) to combine their beneficial features and overcome the limitation of using them individually.

Polymer nanocomposites (PNCs) in which, polymer serves as the matrix while the organic or inorganic material acts as the nanofiller (Sengodu and Deshmukh, 2015) have gained significant industrial and scientific attractions, because of their unique physiochemical properties, emerging from the combination of polymer and nanomaterial, that cannot be obtained with individual components acting alone. PNCs exhibit enhanced functionalities and related advantages rather than native polymers including cost-

effectivity, environmental stability, permeability (for water and gases), electrical conductivity, high strength, high elastic modulus, large surface to volume ratio, large flame retardancy, and enhanced mechanical, thermal, optoelectronic, and magnetic properties (Safdari and Al-Haik, 2013; Rafiee *et al.*, 2009; Mansor and Akop, 2020; Kumar *et al.*, 2013). These tremendous properties have made PNCs good choices for their use in diversified industrial fields including water and wastewater treatments.

The purpose of this article is to focus on the types of PNCs that are applicable in industrial effluent treatments followed by a detailed explanation of their fabrication methods (melting-based methods, solvent-based methods, and in-situ methods) and their implementation for effluent applications (membranes, adsorbents, photocatalyst, disinfectants, and sensors).

Types of Polymer Nanocomposites Relevant for Effluent Processing

PNCs are a combination of a polymer matrix (natural/synthetic) and a filler (organic/inorganic). The fillers have usually one dimension in the nanoscale (clay minerals), two dimensions in the nanoscale (carbon nanotubes (CNTs), nanofibers, nanowires, etc.), or three dimensions in the nanoscale (silica nanoparticles (NPs), etc.) (Azeez *et al.*, 2013; Soetaredjo *et al.*, 2018).

As noted earlier, adsorption is one of the most efficient and cost-effective processes for the purification of wastewater (Singh *et al.*, 2018) and based on the recent studies, nanoclays have earned more attraction for adsorbing various pollutants from the wastewater in comparison with other commercially available adsorbents. This is because of their wide availability, relatively low cost, relatively low environmental impact, and superior surface sorption mechanism (Guo *et al.*, 2018). Different clay minerals can be used as fillers to enhance the absorption of contaminants such as metallic ions and dyes. The adsorption properties of clay minerals can often be improved through mixing with other materials such as polymer, forming polymer-clay nanocomposites (PCNCs) (Awasthi *et al.*, 2019). The clay minerals used for the development of PCNCs are crystalline structures mainly composed of tetrahedral (SiO_4)⁴⁻ and octahedral ($\text{AlO}_3(\text{OH})_3$)⁶⁻ sheets (Mukhopadhyay *et al.*, 2020). They are mainly divided into seven groups, namely kaolinite group (e.g., kaolinite, halloysite, serpentine) (Miranda-Trevino and Coles, 2003), non-expanding group (e.g., mica and illite), limited expanding group (e.g., vermiculite), strongly expanding group (e.g., montmorillonite (MMT)), uncharged group (e.g., pyrophyllite and talc), 2:1:1 group (e.g., chlorites), and fibrous-layered silicates (e.g., palygorskite and sepiolite) (Lee and Tiwari, 2012; Mukhopadhyay *et al.*, 2020).

One of the most essential clay minerals for the development of PCNCs is MMT in smectite groups that belong to the family of 2:1 phyllosilicate. They are composed of two silica-based tetrahedral sheets with water molecules within the interlayer sheets and are easily available for incoming contaminants (Rajapaksha *et al.*, 2019). MMT has a hydrophilic nature, so it is required to modify its surface to make it organophilic/hydrophobic, before preparation of PNCs. Different organic cations are widely used as surface modifiers of MMT clays such as silane and aluminum salts (Huskić *et al.*, 2013; Khajepour *et al.*, 2015; Davis *et al.*, 2003).

Another widely used nanofiller for the preparation of polymeric nanocomposites is carbon nanotubes (CNTs). Carbon-based nanomaterials were first discovered in 1988 with the discovery of buckyball, a molecule made of pure carbon with ball shape, by Kroto *et al.* (1985). Another important discovery was reported by Iijima in 1991, as he reported the discovery of CNTs, a tubular form of carbon (Iijima, 1991). There are many ways for the preparation of CNTs, the most widely used ones are chemical vapor deposition (CVD), sol-gel method, arc discharge method, laser ablation method, and flame synthesis (Khare and Bose, 2005). CNTs that can be used as fillers of PNCs are mainly divided into two groups of single-walled carbon nanotubes (SWCNTs) and multi-walled carbon nanotubes (MWCNTs), based on the number of graphite layers on the wall of the CNTs (Rahmandoust and Ayatollahi, 2016). CNTs have been used for a variety of applications due to their excellent thermo-mechanical and electrical properties (Basheer *et al.*, 2020). Dispersion of CNTs into the polymer matrices increases the adsorption performance of PNCs (Shabaan *et al.*, 2020; Zhuang *et al.*, 2020; Rodríguez and Leiva, 2020; Bassyouni *et al.*, 2020). Bin-Dahman *et al.* investigated the batch adsorption performance of a hybrid material, oxidizing CNT grafted with polyethylene glycol (PEG) (CNT/PEG), for the removal of phenol from wastewater. They found that the adsorption performance of CNT/PEG under optimum conditions was high ($\approx 100\%$) for phenol removal at a contact time of 30 min. They also demonstrated that the prepared hybrid material (CNT/PEG) was an efficient adsorbent for removal of phenol from water as well as for simultaneous removal of phenol with metallic ions such as Cu, Hg, Cr, Fe, Co, Ni, Al, and Pb from industrial effluents (Bin-Dahman and Saleh, 2020). Another important application of polymer grafted CNTs is the water/oil separation membranes. Gu *et al.* developed a simple and robust method to fabricate Janus polymer/CNT hybrid membranes for oil/water separation. They prepared a membrane by dispensing hydrophobic poly (styrene) (PS) and hydrophilic poly(N, N-dimethylaminoethyl methacrylate) (PDMAEMA) that were grafted from different sides of the photoactive CNT membranes via self-initiated photo grafting and photopolymerization (SIPGP). The produced membranes demonstrated excellent selectivity for the removal of oil from water. They also separated both surfactant-stabilized oil-in-water and water-in-oil emulsions effectively, attributed to their anisotropic wettability (Gu *et al.*, 2014).

In recent years, 2D carbon-based nanomaterials such as graphene, graphene oxide (GO), and reduced graphene oxide (RGO) have gained the attention of scientists to use them as fillers for the preparation of PNCs, as the adsorbent for efficient removal of contaminants from wastewater (Yan *et al.*, 2016). These materials possess unique properties such as large surface area, high porosity range, exceptional mechanical strength, and abundant oxygen-containing functional groups such as hydroxyl, carbonyl, epoxy, and carboxylic groups which make them suitable for the fabrication of membranes. Besides, GO can be synthesized from low cost and available graphite (Bera and Maji, 2017). The RGO that contains very low oxygen-containing functional groups is obtained by simple reduction of GO, compatible with less polar or nonpolar organic polymers. As an adsorbent of organic dyes

from wastewater, GO/polyethylenimine (PEI) hydrogels can be effectively used. Graphene-based polymeric nanocomposites can also be used to remove harmful metal ions such as lead (II) and chromium (VI) from wastewater. The graphene-based polymeric nanocomposite membranes such as polysulfone (PSF)/graphene and cellulose/graphene composite membranes are other important adsorbents that have been recently used for the purification of wastewater (Bera and Maji, 2017).

Other nanomaterials that have been widely used in the preparation of polymeric nanocomposites for wastewater treatment are ZnO (Sheikh *et al.*, 2020; Nerkar *et al.*, 2018), porous silica (Betiha *et al.*, 2020), Fe₃O₄ (Badrudodoza *et al.*, 2013), hydroxyapatite (Pai *et al.*, 2021), TiO₂ (Vellaichamy *et al.*, 2017; Hou *et al.*, 2017), and Zr (Gupta *et al.*, 2014) NPs. Gupta *et al.* investigated the adsorption of methylene blue (MB) dye from water systems using novel polyaniline zirconium (IV) silicophosphate (PANI-ZSP) nanocomposite material. They prepared the PNC material by mixing polyaniline (PANI) polymer with the inorganic counterpart (ZSP) using the sol-gel method at 0–1 pH. Their results indicated the PANI-ZSP nanocomposite as an efficient adsorbent for the removal of MB dye from wastewater (Gupta *et al.*, 2014). In another paper, Vellaichamy *et al.* synthesized a new polymeric nanocomposite, PANI/manganese dioxide/titanium dioxide (PANI/MnO₂/TiO₂), using an in-situ method for reduction of toxic Cr⁶⁺ present in the wastewater to Cr³⁺. They claimed that the prepared nanocomposite exhibited a superior catalytic activity in the conversion of toxic Cr⁶⁺ to benign Cr³⁺ in comparison with other nanocomposite materials reported with an excellent conversion of 99.9% (Vellaichamy *et al.*, 2017).

Another classification of PNCs for application in the treatment of effluents is based on polymer matrices. Polymeric materials are divided into two groups of natural and synthetic polymers. Natural polymers can occur in plants or animals while synthetic polymers are derived from petroleum oil and can be artificially produced in laboratories (Shrivastava, 2018).

Different types of natural polymers are used as polymer matrices for wastewater treatment, such as cellulose (Shi *et al.*, 2020), starch (Ahmad *et al.*, 2020), chitin (Perez *et al.*, 2020), chitosan (Rani *et al.*, 2020), gelatin (Ahmad *et al.*, 2020), alginate (Esmat *et al.*, 2017), pectin (Gupta *et al.*, 2012) and guar gum (Pathania *et al.*, 2016; Patra *et al.*, 2017; Zahran and Marei, 2019; Nasrollahzadeh *et al.*, 2021).

Shi *et al.* developed Ag–ZnO/cellulose nanocomposites via tunable cellulose size for improving photocatalytic performance. They controlled the diameter distribution of cellulose by grinding them 10, 20, and 30 times which resulted in average fibril diameters of 130, 64, 42 nm, respectively. Their PNC exhibited excellent photocatalyst activity for the degradation of methyl orange (MO) present in wastewater. Besides, their PNC demonstrated outstanding stability and reusability even after 10 cycles of use (Shi *et al.*, 2020).

In another study, Azizi synthesized Fe₃O₄/cellulose nanocomposites for the removal of metronidazole from aquatic solutions by the adsorption method. They evaluated the adsorption capacity of their PNC by optimizing four important parameters including pH, initial concentration of metronidazole, amount of nanocomposite, and contact time. Their results indicated that the PNC had a high removal efficiency of 97.04% at the optimal operating conditions, demonstrating it as a suitable adsorbent for environmental applications (Azizi, 2020).

Rani *et al.* synthesized iron-oxide-based chitosan-nanocomposites via green route for photo-oxidative degradation of polycyclic-aromatic-hydrocarbons (PAHs) such as anthracene (ANTH) and phenanthrene (PHEN). The highest degradation was observed for ZnFe₂O₄-CS (ANTH: 95%, PHE: 92%) followed by CuO-Fe₂O₃-CS (93%, 90%), NiFe₂O₄-CS (90%, 88%), Co₂O₃-Fe₃O₄-CS (88%, 85%) and FeCr₂O₄-CS (83%, 81%), respectively. They indicated the insight on preparing effective, green, reusable ($n = 10$), stable nanocomposites for the removal of carcinogenic PAHs from wastewater (Rani *et al.*, 2020).

Perez *et al.* synthesized a low-cost and regenerable composite based on chitin/bentonite for the adsorption of pollutants such as trimethoprim (TMP) present in wastewaters. They conducted different characterization tests such as ATR-FTIR, XRD, DSC, and TGA, all of which revealed the intercalation of the chitin macromolecules into the bentonite interlayer. The maximum adsorption capacity of TMP was 67 mg/g, indicated by Langmuir Isotherm. After three regeneration cycles, the sectioned composite reached around 100% adsorption capacity (Perez *et al.*, 2020).

Polar and non-polar synthetic polymer matrices can provide some properties that make PNCs suitable for application in different wastewater treatment such as membrane filtration, adsorption, photocatalyst, microbial and control agent, and sensing and monitoring of contaminants. Some examples of synthetic polymers are high-density polypropylene (HDPE) (Amini *et al.*, 2017), low-density polyethylene (LDPE) (Romero-Sáez *et al.*, 2017), polyvinyl alcohol (PVA) (Isawi, 2020; Mahdavinia *et al.*, 2017), PEG (Khalid *et al.*, 2018; Saeedi-Jurkuyeh *et al.*, 2020), polyacrylic acid (Rafei *et al.*, 2016; Sun *et al.*, 2015), polyesteramide (PEA) (Soetaredjo *et al.*, 2018), and polypyrrole (PPy) (Aigbe *et al.*, 2018).

Aigbe *et al.* developed different PNCs by dispersion of various nanofillers such as zinc oxide (ZnO), silicon dioxide (SiO₂), titanium dioxide (TiO₂), GO, and aluminum oxide (Al₂O₃) into the polyethersulfone polymer matrix to produce a mixed-matrix membrane. They also compared the effect of different nanofillers and the efficiency of the developed membranes for the removal of rhodamine B (RhB) dye from textile wastewaters. Based on their observations, all of the membranes exhibited high RhB removal efficiency of 91.96%–96.92% (Aigbe *et al.*, 2018).

The removal of brilliant green dye from the wastewater was investigated by Shirsath *et al.*, using a poly(acrylic acid) hydrogel composite (PAA-K hydrogel) prepared by incorporation of kaolin clay. They reported that the PNC had high dye adsorption at the optimum condition with a pH of 7, a temperature of 35 °C, an initial dye concentration of 30 mg/L, and hydrogel loading of 1 g (Shirsath *et al.*, 2013).

Shokri *et al.* developed fouling resistant and highly permeable polyvinyl chloride (PVC) ultra-filtration membranes by dispersing different amounts of natural and modified MMTs with folic acid (Mt-FA). Modification of MMT with folic acid resulted in better dispersion of MMT in the polymer matrix. Their results revealed that all PNC membranes showed hydrophilicity and roughness compared with neat PVC. Besides, their results demonstrated that the incorporation of MMT NPs into the polymer matrix enhanced the pure water flux, porosity, mechanical strength, and reusability of the membranes (Shokri *et al.*, 2020).

Fabrication Methods of Polymer Nanocomposites

After selecting the desired NPs with an acceptable level of compatibility with the polymer matrix to develop a PNC, it is necessary to choose the best fabrication method to obtain a uniform distribution and dispersion of NPs in the polymer matrix, without any aggregation. The common fabrication methods of PNCs are divided into three main categories of melting-based, solvent-based, and in-situ methods, each of them has multiple subcategories described as follows.

Considering the purpose of this article to focus on the PNCs which are applicable in the industrial effluent treatments, all of the fabrication methods of the PNCs are given in this section with a detailed explanation since there is no significant difference between the synthesis methods of the efficient PNCs for effluent treatments and that of the inefficient ones. In the present section, we have tried to cover all of the fabrication methods, although some of them may not be used in the case of the special PNCs with the application in effluent processing, to ensure mentioning the fabrication methods of the applicable PNCs that might not be mentioned in this work. Then in Section “Implementation of Polymer Nanocomposites for Effluent Applications”, the applicable PNCs in the treatment of effluents along with their method of fabrication are introduced and for more details about synthesis methods, it is required to refer to the present section.

Melting-Based Methods

Melt blending method

In this method, the polymer powder is melted to obtain a viscous solution and the nanofillers are then added into the polymer solution and dispersed under a high shear rate and high-temperature diffusion to reduce the size of possible agglomerates, using single or twin-extruders (Mallakpour and Naghdi, 2018). The strain applied to the NPs by the polymer depends on the polymer molecular weight and weight distribution. First, by applying the high shear rates, the large agglomerates are breakdown and form smaller ones that dispersed within the polymer matrix (Fig. 1a). The transferred strain from polymer to the new smaller agglomerates leads to a stronger shearing that breaks the agglomerates into the individual particles, which strongly depends on the time and chemical affinity between the polymer and NPs' surface (Fig. 1b) (Mistretta *et al.*, 2014). Finally, the individual NPs are separated and diffused in the melted polymer matrix (Fig. 1c). The final shape of the nanocomposites can be fabricated by compression molding, injection molding, or fiber production techniques. The melt blending method is one of the popular fabrication methods of PCNCs. Some of the common advantages of this technique are its cost-effectivity, ecofriendly, high heat stability, good mechanical properties, and high compatibility with industrial operations such as extrusion and injection molding to be commercialized (Mallakpour and Marefatpour, 2014; Dong *et al.*, 2012; Mallakpour and Naghdi, 2018). The big limitation of this method is the need for high temperature which may have a detrimental effect on the polymer matrix and also on the modified surface of the nanofillers. Besides, the interaction between polymer and NPs is not easy to control in this method, and consequently, it may be difficult to obtain a good dispersion of the nanofillers (Fischer, 2003; Tanahashi, 2010).

Melt mixing method

Similar to the previous, the polymer is melted in this method. To achieve an acceptable dispersion of nanofillers in the melt solution, a high-shear mixing and a proper choice of polymer and compatibilizer/surfactant are required. The purpose of using a compatibilizer is to control the melt solution viscosity since the addition of nanofillers significantly increases its viscosity. The melt mixing method is one of the appropriate fabrication methods of insoluble or immiscible polymers (Goyal, 2017). Some of the

Fig. 1 Effect of shear stress on NP dispersion during melt blending. Reproduced from de Oliveira, A.D., Beatrice, C.A.G., 2018. Polymer nanocomposites with different types of nanofiller. In: Sivasankaran, S. (Ed.), Nanocomposites-Recent Evolutions. IntechOpen. pp. 103–104.

main benefits of this technique are cost-effectivity, ecofriendly, simplicity, and availability. Similar to the melt blending method, the big limitation of this technique is the usage of high temperatures. Besides, despite the positive effect of high shear mixing on achieving good dispersion of nanofillers, it reduces the aspect ratio of the nanofillers, having a negative effect on enhancing the nanocomposite properties. Consequently, the choice of a proper value of shear rate to obtain a good dispersion without any negative effect on the aspect ratio is still a challenge of this method (Feng *et al.*, 2014). Furthermore, it is usually required to chemically treat the surface of the nanofillers to obtain proper compatibility with the polymer matrix and good dispersion.

Melt compounding method

In this method, nanofillers are added to the polymer melt solution above the glass transition temperature (T_g). A high shear rate is induced in the polymer melt by viscous drag to breakdown the nanofiller aggregates and obtain a uniform homogeneous dispersion in the polymer matrix. Melt compounding is a simple and cost-effective method to fabricate high-performance PNCs. The critical threshold shear stress value that is necessary for breaking down the nanofillers agglomerates is the main factor to control the dispersion state of the fillers in the melt-compounding method.

Melt intercalation method

In this method, the polymer matrix is annealed at the molten temperature, the fillers are added and the mixture of polymer and nanofillers are kneaded either statically or under shear to reach a uniform distribution. Dispersion of nanofillers in the polymer matrix occurs in four steps: (1) wetting of the initial nanofillers agglomerates by the polymer, (2) infiltration of the polymer chains into the initial agglomerates to weaken them, (3) breaking down and disruption of the agglomerates to reach a smaller one, and (4) dispersion and distribution of individual nanofillers into the polymer matrix. The nanofillers dispersion depends on different factors such as processing conditions, surface modification of the nanofillers, and the compatibility between the fillers and polymer matrix. The melt intercalation is a typical fabrication method of thermoplastic PNCs and depending on the electrostatic forces among the filler interlayers and the compatibility with the polymer matrix, an intercalated or exfoliated morphology will be formed. Some of the common advantages of this method are cost-effectivity, ecofriendly, compatibility with the industrial processes such as extrusion and injection molding, and easy to commercialized. The only limitation is the usage of high temperatures that can damage the polymer chains and the modified surface of the nanofillers. As an instance, the surface of organoclay nanofillers that is usually modified with alkyl ammonium decomposes at temperatures higher than 140 °C, while the required temperature of melt intercalation is in the range of 190–220 °C. The usage of more thermally stable surface modifiers along with operating at lower temperatures are some of the proposed methods to address this limitation.

Solvent-Based Methods

Solvent method

In this method, the NPs and polymer are dispersed in a solvent and co-solvent, respectively. The dispersion of nanofillers in the solvent is conducted by sonication to breakdown the nanofillers aggregates. The resulting nanocomposite is then recovered from the solvent via solvent evaporation/coagulation. The induced shear rate on the polymer matrix in this method is lower than the case of the melt compounding method (Jannapu Reddy, 2010).

Solution method

In this method, both polymer and nanofillers are dispersed in a common solvent, despite the solvent method in which a solvent and a co-solvent are required. The resulting nanocomposite is then recovered from the solvent by filtration, precipitation, or film casting. Some of the most common polymers that can be dissolved in organic solvents are polycarbonate, polystyrene, polymethylmethacrylate (PMMA), and PVA. Although the solution method is a simple process, it requires a large amount of solvent that may be dangerous for the environment (Goyal, 2017).

Fig. 2 Schematic illustration of the solution blending method. Reproduced from de Oliveira, A.D., Beatrice, C.A.G., 2018. Polymer nanocomposites with different types of nanofiller. In: Sivasankaran, S. (Ed.), Nanocomposites-Recent Evolutions. IntechOpen. pp. 103–104.

Solution blending method

In this method, the polymer and nanofillers are dispersed in an appropriate solvent. The dispersion of nanofillers can be done via different methods of ultrasonic irradiation, magnetic stirring, or shear mixing (Passador *et al.*, 2017; Naz *et al.*, 2016). The NPs will then remain dispersed into the polymer chains after solvent evaporation resulting in a nanocomposite, schematically shown in Fig. 2. The solution blending is a suitable fabricating method for both thermoplastic and thermoset polymers in the case of all nanofillers. Some of the benefits of this method are easy operation and low gas permeability and the main limitation is the usage of expensive solvents, providing problems from both economic and environmental points of view (Kango *et al.*, 2013; Bhattacharya, 2016).

Solution mixing method

In this method, the nanofillers are swollen in a solvent and the polymer is dissolved in a co-solvent. The two solutions are then mixed and the polymer chains intercalate and displace the solvent within the interlayer of the nanofillers. The dispersion of nanofillers in the polymer solution can be occurred by sonication, magnetic stirring, or shear mixing. An intercalated or exfoliated nanocomposite will remain after solvent evaporation (Rane *et al.*, 2018; Gurses, 2015).

Exfoliation adsorption

In this method, which is also called the polymer/prepolymer intercalation from the solution, the layered nanofillers are first swollen and dispersed in a solvent and the polymer is dissolved in a co-solvent. The polymer chains intercalate and displace the solvent within the interlayer of nanofillers and a multilayer structure will be then formed after solvent removal. The driving force behind this method is the entropy gained by solvent desorption, compensating the entropy reduction caused by the confined intercalated chains. The exfoliation adsorption is a common method of fabricating intercalated PNCs based on the water-soluble polymers and the polymers with little or no polarity such as poly(vinyl alcohol), poly(ethylene oxide), poly(vinylpyrrolidone), or poly(acrylic acid). The main limitation of this method is the usage of a large amount of solvent which is environmentally unfriendly (Ray and Okamoto, 2003; Pavlidou and Papaspyrides, 2008). This method can be subdivided into two methods of solution intercalation and in-situ polymerization both of which are described below.

Solution intercalation method

In this method, the layered nanofillers are dispersed in a solvent in which the polymer is also soluble and exfoliated into the single layers. The polymer chains are then adsorbed onto the delaminated sheets and the sheet reassemble after the solvent evaporation, sandwiching the polymer to form an ordered, multilayered structure (Koo, 2006). The general required steps in the solution intercalation method are (1) dispersion of nanofillers in a solvent by agitation, (2) mixing the nanofillers and polymer solutions by agitation, and (3) controlled evaporation of the solvent and/or precipitation of nanocomposite (Shawky *et al.*, 2011).

Emulsion polymerization

In this method, the layered nanofillers are dispersed in an aqueous phase similar to the solution intercalation method and the polymer monomers are dispersed in water with an emulsifier. The monomers are then polymerized with a part of the NP embedded inside the polymer particle and a part adsorbed on the particle surface, forming a nanocomposite.

Sol-gel method

This method is associated with two relation steps; “sol” as a colloidal suspension of solid NPs dispersed in the monomer solution, and “gel” as a three-dimensional interconnecting network formed between phases by polymerization reactions followed by hydrolysis procedure. This three-dimensional network of polymer NPs spreads across the liquid and the polymer acts as a nucleating agent to enhance the growth of layered crystals. As the crystals grow, the polymer seeps between the layers, forming a nanocomposite (Jannapu Reddy, 2010).

In-Situ Methods

In-situ formation

In this method, the dissolved monomers in an aqueous solution are embedded on the sol-gel matrices and organic groups are then introduced via chemical bonds, leading to the in-situ formation of the sol-gel matrix within the polymer and simultaneous generation of a three-dimensional network. During the process, polymer aids the growth of inorganic host crystals and gets trapped within the nanolayers as they grow. This is a common fabrication method of layered double hydroxide (LDH) nanocomposites (Rane *et al.*, 2018).

In situ template synthesis

In this method, the polymer matrix and nanolayers are dissolved in an aqueous solution. By trapping the polymer chains inside the nanolayers, the nanolayers are nucleated and grown on the polymer chains at high temperatures. The main limitation of this method is the high operating temperature which may degrade or decompose the polymer (Khan *et al.*, 2016).

Fig. 3 Schematic illustration of the in situ intercalative polymerization method. Reproduced from de Oliveira, A.D., Beatrice, C.A.G., 2018. Polymer nanocomposites with different types of nanofiller. In: Sivasankaran, S. (Ed.), *Nanocomposites-Recent Evolutions*. IntechOpen. pp. 103–104.

In-situ intercalative polymerization method

In this method, the monomers are dissolved in a solution and by adding the nanofillers, the low molecular weight monomer solution easily seeps in between the nanolayers, resulting in their swelling. The migration of monomers into the galleries of nanolayers leads to the polymer formation between the intercalated sheets. The polymerization process can be initiated via different methods such as heat/radiation, diffusion of a suitable initiator such as organic ones, and catalysts fixed through cationic exchange inside the interlayer before the swelling of nanofillers. The polymerization of monomer between the interlayers will thereby form an intercalated or exfoliated nanocomposite (Karimi and Wan Daud, 2017) with a schematic illustration of the process shown in Fig. 3. The proper dispersion of nanofillers in the monomer solution before the polymerization process is a critical factor to guarantee the polymer formation between the NPs. Modifying the surface of the NPs by organic modifiers facilitates the better dispersion of NPs and the polymerization process. The in-situ intercalative polymerization is a proper fabricating method of both thermoplastics and thermoset polymers, and also the non-soluble and thermally stable PNCs. Some of the benefits of this method are cost-effectivity, high transparency, good dispersion of nanofillers, controllable particle morphology, and high interfacial adhesion of the nanofillers to the polymer matrix. Besides, it is possible to easily disperse higher content of nanofillers without any agglomeration compared to the case of melting methods in which the nanofiller dispersion is somewhat difficult due to the high viscosity of the solution. A high-performance nanocomposite will be then obtained due to the presence of a covalent bond among the NP functional groups and the polymer chains.

Implementation of Polymer Nanocomposites for Effluent Applications

Concerning the high importance of treating huge amount of industrial effluents that are annually released into the environment because of the rapid development of industrialization, different methods are available for the decontamination of the wastewater (Soetaredjo *et al.*, 2018; Rajasulochana and Preethy, 2016; Barakat, 2011), among which PNCs have attracted great attention because of their cost-effectivity, eco-friendly, and unique properties.

Polymer Nanocomposites as Adsorbents

Adsorption technique is one of the most commonly used techniques for the wastewater treatment. This technique is considered as a low-cost, simple, quick, and effective way of removing various kinds of organic and inorganic pollutants such as heavy metals (Ravikumar and Udayakumar, 2020; Zhang *et al.*, 2020), dyes (Yadav *et al.*, 2020), phenols (Hatami *et al.*, 2020; Bin-Dahman and Saleh, 2020), oil and grease (Lü *et al.*, 2016; Yu *et al.*, 2015), pharmaceuticals (Zhang *et al.*, 2016), and several other contaminants (Akhrame *et al.*, 2018). PNCs are considered as a high potential adsorbent for water and wastewater treatments as they possess extremely high surface area and associated sorption sites, short intraparticle diffusion distance, and tunable pore size and surface chemistry (Qu *et al.*, 2013).

Ptaszkowska-Koniarz *et al.* studied the adsorption of rhodamine B and sunset yellow FCF from the liquid phase onto resorcinol (Aldrich) and formaldehyde (Chempur) modified with methylamine and copper (II) chloride. They prepared the PNC based on the conventional sol-gel method. They found that the adsorption capacity towards rhodamine B and sunset yellow depended on some factors such as pH, temperature, and modification of materials using acid or bases. The adsorption capacity toward the removal of dyes increased by temperature increment of the process. The acidic medium helped the effective removal of the sunset yellow FCF, while the basic medium helped that of rhodamine B. They also proved that the modification of PNC increases the effective adsorption of dyes (Ptaszkowska-Koniarz *et al.*, 2017).

Horst *et al.* studied batch adsorption of heavy metal ions on magnetic/chitosan nanocomposites. The maximum adsorption capacity for removal of Zn, Cu, Cd, and Cr were respectively 72, 188, 159, and 46 (mg/g), which were considerably higher than those reported in the literature. The results also indicated that the adsorbents had satisfactory reusability with 5–8 reuse cycles. This allows their application in the removal of contaminants from water and wastewater (Horst *et al.*, 2016).

Lee *et al.* studied the removal of Cr(VI) ion from aqueous solution using polymer-based adsorbents. They used alginate/PVA-hematite nanocomposite which was prepared by entrapping a powdered form of hematite in alginate and PVA blend

hydrogels. The results showed that the maximum sorption capacity of the PNCs toward Cr(VI) was 12.501 mg/g. They found that Cr(VI) removal was highly sensitive to a pH between 2 and 9, and the highest removal capacity of adsorbents occurred at the highest acidic solution pH, decreasing sharply with increasing pH (Lee *et al.*, 2013).

Shahzad *et al.* investigated the removal of heavy metals, such as Pb(II), Cu(II), and As(III) from aqueous solutions using (EDTA)-functionalized magnetic chitosan GO nanocomposites. They prepared (EDTA-MCS/GO) using a reduction precipitation method. Their results indicated that the nanocomposite had an excellent removal ability with a maximum adsorption capacity of 206.52, 207.26, and 42.75 mg/g over Pb(II), Cu(II), and As(III), respectively. It was also found that various operating parameters, such as pH, temperature, metal ion concentration, and contact time influenced the adsorption effectiveness (Shahzad *et al.*, 2017).

Arya and Philip studied the removal of pharmaceuticals from wastewater using PNCs. They prepared clay: chitosan: powdered activated carbon: magnetic NPs nanocomposite adsorbent for removal of atenolol, ciprofloxacin, and gemfibrozil from wastewater. They also investigated the influence of solution pH, NP loading amount, and the acid or base used for modification of nanocomposite on the adsorption process. Results showed the successful application of magnetic chitosan nanocomposites for the removal of atenolol, ciprofloxacin, and gemfibrozil from the wastewater with a maximum adsorption capacity of 15.6, 39.1, and 24.8 mg/g, respectively (Arya and Philip, 2016).

Polymer Nanocomposites as Membrane Filters

In recent years, the usage of nanocomposite membranes has attracted the attention of scientists for the treatment of water and wastewater since the existing membranes, mainly polymers in nature, are still restricted by several challenges, including the trade-off between permeability and selectivity and low resistance to biofouling. PNC membranes are used for the removal of micro-organisms, chemical compounds, heavy metals, and other pollutants from waste streams such as agro-food (Cassano *et al.*, 2018), textile (Van der Bruggen *et al.*, 2004), petroleum industries (Parsaie *et al.*, 2020) or drinking water streams (Mukhopadhyay *et al.*, 2020). The nanocomposite membranes can be designed for different purposes by tuning their structure and physiochemical properties, such as hydrophilicity, porosity, charge density, and thermal and mechanical stability, leading to unique physiochemical properties such as excellent chemical and mechanical stability, electrical conductivity, reinforcement capability, and antifouling properties.

Generally, nanocomposite membranes are either produced by dispersing NPs into a polymer matrix or coating onto the membrane surface (Ursino *et al.*, 2018). Nor *et al.* prepared a nanocomposite membrane consisting of Polyvinylidene Fluoride (PVDF) and electrospun titanium dioxide (TiO₂) nanofibers, (PVDF/e-TiO₂), by hot pressing the as-spun TiO₂ nanofibers onto the PVDF flat sheet membrane. The TiO₂ nanofibers acted as photocatalysts to decompose the organic pollutants in the wastewater and the PVDF membrane acted as a support. The plate containing the TiO₂-PVDF membrane was placed in a hydraulic press system and pressed under a pressure of 80 bars. The hot press technique was carried out by setting the operating temperatures at 60 °C, 100 °C, 160 °C, and 180 °C for about 30 min. It was shown that the nanocomposite membrane prepared at a hot-pressing temperature of 100 °C exhibited appropriate morphological structure and physical properties. PVDF/e-TiO₂-100 exhibited the highest photocatalytic activity in the degradation of bisphenol A (BPA) under UV irradiation compared to PVDF/e-TiO₂-160 and PVDF/e-TiO₂-180. Their results also indicated that the introduction of TiO₂ nanofibers in PVDF-based nanocomposite membrane via hot pressing plays an important role in enhancing the degradation and filtration of organic pollutants such as BPA (Nor *et al.*, 2016).

In another study, Qin *et al.* prepared a new nanocomposite forward osmosis membrane (FO) for the simultaneous removal of oil and salt from shale gas wastewater. The prepared nanocomposite FO membrane was composed of an oil-repelling and salt rejecting hydrogel selective layer on top of GO nanosheets infused polymeric support layer. It was shown that the hydrogel selective layer leads to superior anti-fouling capability under any oil-water emulsions. On the other hand, this new FO membrane demonstrated more than three times higher water flux and higher removal for oil and salts (>99.9% for oil and >99.7% for multivalent ions). Results indicated that this new FO membrane has the merit to find application in treating highly saline and oily wastewater (Qin *et al.*, 2015).

Amoli-Diva *et al.* reported the preparation and characterization of PSF nanocomposites in which silver, cobalt, and nickel NPs were incorporated into the PSF materials for ultra-purification of wastewater. To prepare the nanocomposite membrane, PSF was dissolved in N, N-dimethyl acetamide (DMAc) and its surface was modified by adding 10% of the cobalt NPs and the solution was sonicated until forming a uniform homogenous casting suspension. Their results showed that PSF/Ni in the aqueous medium had the highest diffusion coefficient, the smallest particle size, and the smallest pore size compared to other prepared PSF thin-film membranes. Moreover, their results indicated that the pore size distribution influences the hydrophobic nature of the membrane as well as the diffusion behavior at the membrane interface. They proved that the diffusion coefficient may be used as an indication of the hydrophilicity of the membrane for the aqueous systems. Overall, it was shown that the incorporation of Ni and Co NPs into the modified PSF materials leads to a reduction in membrane fouling behavior (Amoli-Diva *et al.*, 2020).

In another study, Rahimi *et al.* fabricated an antifouling nanocomposite membrane from goethite (α -FeOOH) and polyethersulfone. It was reported that not only the membrane possessed excellent antifouling properties in long-term exposure with protein solution but it also showed a good selectivity and high dye removal capacity for Direct Red 16 (99%) (Rahimi *et al.*, 2016).

Lü *et al.* synthesized a thermosensitive poly(N-isopropylacrylamide)-grafted magnetic NPs (MIO@SiO₂) PNC to demulsify the oily droplets present in wastewater. The membrane showed very good oil removal from the aqueous solution and also a great ability to be reused with over 90% transmittance after the 7th reuse cycle (Lü *et al.*, 2016).

In another work, Qiu and He presented a new and efficient strategy to modify the nanocomposite membrane and constructed a zwitterion-silver nanocomposite structure via second interfacial polymerization of zwitterion and in-situ synthesis of silver NPs (Ag NPs). Results showed that compared with existing data reported in the literature, the modified zwitterion-silver nanocomposite membrane showed outstanding antifouling property (> 96% antimicrobial efficiency), high water flux, and excellent selectivity, which highlights its potential for practical applications (Qu and He, 2018).

Polymer Nanocomposites as Photocatalyst

Photocatalytic or catalytic oxidation is a process that is used to remove trace contaminants and microbial pathogens from wastewater. The use of PNCs with high surface area per volume in the photocatalytic process for the removal of pollutants from the wastewater is one of the most appealing and highly investigated research areas due to its great potential and high efficiency using sunlight to remove the organic pollutants and harmful bacteria. The use of sunlight as an energy source is an ideal method as it is a safe, renewable, and clean method (Dong *et al.*, 2015).

To prepare the PNCs for photocatalytic purposes, several kinds of polymers such as hyperbranched polyester, polyamide, poly(vinylidene difluoride)-*co*-trifluoroethylene, polyethersulfone, polyetherimide, polypyrrole, and polyvinyl alcohol (Akhrame *et al.*, 2018) and several kinds of fillers (considered as photocatalyst) such as ZnO, RGO, SnO₂, CeO₂, and TiO₂ can be used. Among fillers, TiO₂ is the most widely studied photocatalyst because of its non-toxicity, cost-effectivity, high chemical and photochemical stability, and unique photocatalyst efficiency (Dong *et al.*, 2015).

Photocatalytic degradation of inorganic pollutants

Yu *et al.* prepared BiPO₄-PANI heterostructure by hydrothermal method and hybridization. Their experimental results showed that BiPO₄-PANI could degrade several typical pollutants such as heavy metal ions and organic dyes under visible light. Based on their observations, PANI/BiPO₄ had an excellent ability for degradation of Hg(II) (95.3%), Cr(VI) (97.7%), and MB dye (95.8%) under 300 W xenon lamp (Yu *et al.*, 2018).

In another work, Shirmardi *et al.* studied the effect of PANI as an organic semiconductor on the photocatalytic performance of ZnSe NPs. They prepared Pristine ZnSe NPs and ZnSe/PANI nanocomposites by a simple and cost-effective co-precipitation method in the ambient conditions. The results showed an enhancement in the photocatalytic performance of ZnSe/PANI nanocomposites compared to the pristine ZnSe NPs for the conversion of Cr(VI) to Cr(III) in the aqueous solution (Shirmardi *et al.*, 2018).

Photocatalytic degradation of organic pollutants

Shanmugam *et al.* synthesized graphene-TiO₂ nanocomposites with enhanced photocatalytic properties for the degradation of organic pollutants present in wastewater. The G-TiO₂ nanocomposites were synthesized by the one-pot in-situ microwave method which is a novel surfactant-free, environmentally friendly method. Experiments showed that the surface area of pure TiO₂ and G-TiO₂ nanocomposite were 20.11 m²/g and 173.76 m²/g, respectively. The photocatalytic activity of the nanocomposites increased greatly due to the increment in the surface area. The results indicated the highest degradation efficiency of 97% by UV light and 96% by visible light irradiation, revealing the G-TiO₂ nanocomposite as an effective catalyst for industrial wastewater treatment both in the UV light and visible light (Shanmugam *et al.*, 2016).

Similarly, Duarah and Karak developed a sustainable hyperbranched polyurethane (HPU) nanocomposite with reduced carbon dot-zinc oxide nanohybrid (RCD-ZnO) as a prospective solar energy-assisted heterogeneous photocatalyst for the degradation of dodecyl benzenesulfonate and commercial detergent upon exposure to sunlight. The RCD-ZnO was fabricated with a starch-based HPU by an in-situ polymerization process. The synthesized PNCs exhibited high degradation of dodecyl benzenesulfonate (96.7% in 110 min) and commercial detergent (94.8% in 150 min) (Duarah and Karak, 2019).

In another work, Kumar *et al.* fabricated a novel photocatalyst polyacrylamide/Ni_{0.02}Zn_{0.98}O (PAM/NZO) by the addition of NPs during polymerization of acrylamide in an aqueous medium using ammonium persulfate and N,N'-acrylamide. The PNC showed high removal efficiency of 99.17% and 96.55% for rhodamine B and malachite green, respectively. The prepared nanocomposite had also a high recycling efficiency (Kumar *et al.*, 2014).

Although TiO₂ is the most popular NP for the fabrication of photocatalysts PNCs in wastewater remediation, other inorganic NPs are also employed for this purpose. Zhao *et al.* synthesized a new type of magnetic photocatalyst graphene/Fe₃O₄/NiO (GNs/Fe₃O₄/NiO) nanocomposite for the removal of organic pollutants in wastewater. They found that the composite materials had a perfect photocatalytic performance to degrade p-nitrophenol and rhodamine B. Moreover, the nanocomposites can be recycled easily by an extra magnetic field after photocatalytic degradation of p-nitrophenol and rhodamine B in wastewater. Therefore, this allows the magnetic nanocomposites to find great potential applications in the photocatalytic field in the future (Zhao *et al.*, 2015).

Romero Saez *et al.* fabricated a PNC photocatalyst using TiO₂ immobilized into LDPE and HDPE (10, 20 wt%) to degrade MO in an aqueous medium under visible light irradiation. TiO₂ was synthesized by the sol-gel process and the polymers were incorporated by impregnation. TiO₂(90)/LDPE photocatalyst showed the best degradation efficiency among all experimented PNCs after 180 min of reaction, without a notorious reduction in the degradation efficiency after three consecutive uses (Romero Saez *et al.*, 2017).

Zarrin and Heshmatpour reported the synthesis of PNCs using $\text{TiO}_2/\text{Nb}_2\text{O}_5/\text{PANI}$ and $\text{TiO}_2/\text{Nb}_2\text{O}_5/\text{RGO}$ nanocomposites for photocatalytic degradation of organic pollutants via the hydrothermal method, accompanied by the in-situ chemical oxidative polymerization. Their results indicated that under visible light the $\text{TiO}_2/\text{Nb}_2\text{O}_5/\text{RGO}$ exhibited significantly higher photocatalytic activity in the degradation of organic dyes (MB and MO dyes) in comparison with $\text{TiO}_2/\text{Nb}_2\text{O}_5/\text{PANI}$, $\text{TiO}_2/\text{Nb}_2\text{O}_5$, and pure TiO_2 (Zarrin and Heshmatpour, 2018).

Photocatalytic disinfection of biological pollutants

Malesic-Eleftheriadou *et al.* synthesized a bio-based polyethylene terephthalate- TiO_2 (PET- TiO_2) photocatalyst to remove antibiotics such as isoniazid, metronidazole, sulfadiazine, sulfamethoxazole, trimethoprim, norfloxacin, moxifloxacin, and lincomycin from the aqueous media. In their study, PET was used and evaluated as a supporting polymer for aerioxide P25 TiO_2 immobilization. Different composites with different TiO_2 content were prepared (10%, 30%, and 47% TiO_2). Results indicated that the immobilization of TiO_2 NPs was successful in all cases and higher photocatalyst concentration resulted in higher photodegradation efficiencies. Finally, it was proved that PET-10%- TiO_2 was efficient in the degradation of the antibiotic mixture present in water and wastewater (Malesic-Eleftheriadou *et al.*, 2019).

Pathania *et al.* prepared PANI zirconium (IV) silicophosphate (PANI-ZSP) nanocomposite via the sol-gel method by mixing PANI gel into the inorganic precipitates of zirconium(IV) silicophosphate (ZSP). Their study revealed that PANI-ZSP nanocomposite had a degradation efficiency of 82% for photocatalysis of MB dye from water and it was successfully used as an antibacterial agent against *Escherichia coli* (*E. coli*) (Pathania *et al.*, 2014).

Yao *et al.* presented the improvement of TiO_2 thin film photocatalytic efficiency under visible light ($\lambda > 400$ nm) by doping a novel photosensitive dye (5, 10, 15, 20-tetraphenyl-21H, 23H-porphine nickel, TPPN), using the sol-gel method. The TiO_2/TPPN thin film had a good inhibition rate for photocatalytic degradation of phytopathogenic bacteria including *Enterobacter cloacae* SM1, *Erwinia carotovora* subsp. *carotovora* 3, and *E. carotovora* subsp. *carotovora* 7 under visible light. These results indicated that TiO_2/TPPN thin film has a potential for the direct application to the plant protection under visible light irradiation in water systems (Yao *et al.*, 2007).

Polymer Nanocomposites as Disinfectants and Microbial Control Agents

It is well recognized that traditional methods such as free chlorine (Cl_2), chlorine dioxide (ClO_2), ozone (O_3), UV, and UV/chlorine (UV/ Cl_2), which are used for the removal of disinfectants and microbial agents might have an adverse effect on the treated wastewater (Luo *et al.*, 2020). Hence, the incorporation of a novel water disinfection method to overcome the limitations encountered by other methods is essential. An alternative method to remove the microbial agents from wastewater is the use of PNCs with MMT, Ag, ZnO, TiO_2 , CNT, and Graphene nanofillers.

Maddigpu *et al.* reported the application of carbon nanoparticles (CNPs) and chitosan (CHIT) in the form of CHIT-CNP nanocomposite for the disinfection of wastewater. The nanocomposite was prepared by the solution casting method. The results indicated that CHIT-CNP nanocomposite had a highly efficient antimicrobial activity for *E. coli* under solar irradiation when used in a recirculating compound parabolic collector (CPC) reactor (Maddigpu *et al.*, 2018).

Mahlangu *et al.* fabricated a dual-purpose magnetic PNC from $\text{Fe}_3\text{O}_4@\text{PPy-MAA}$ via in situ oxidative polymerization of the pyrrole monomer in a thioglycolic acid (mercaptoacetic), acid solution (as a dopant), in the presence of iron oxide (Fe_3O_4). The maximum adsorption capacity of the prepared PNC for Ag^+ was determined to be 833.33 mg/g at room temperature. They showed that the adsorbed Ag^+ can be used for the disinfection of microorganisms such as *E. coli*. Finally, the prepared PNC has an excellent ability for the removal of Ag^+ ions from wastewater, subsequently, the Ag^+ loaded waste material can be used for the disinfection of pollutants (Mahlangu *et al.*, 2019).

Lovatel *et al.* prepared a hybrid PNC from silver nanoparticles (Ag NPs) anchored onto MMT and dispersed in sodium alginate (ALG) polymeric matrix. The hybrid MMT-ALG-Ag NPs were tested for antibacterial activity by the agar diffusion test using two microorganisms (*E. coli* and *S. aureus*). According to their results, a reduction of 98.5% of the total coliforms was observed, which shows a better performance compared to the UV radiation, as a common method for disinfection of industrial wastewater (Lovatel *et al.*, 2015).

Polymer Nanocomposites as Sensing and Monitoring Devices

The growing concern about the public health and the environment has led to the search for effective methods to determine and quantify pollutants in water and wastewater. Due to the extremely low concentrations, high complexity of water/wastewater matrices, and lack of fast pathogen detection, water and wastewater treatment has faced a challenge in sensing and monitoring contaminants. Thus, the development of an accurate and high-quality method of monitoring the contaminant concentration is currently crucial. Several types of research have been done regarding PNC-based electrochemical and photochemical devices for water testing, among which the use of PNCs possesses unique properties such as excellent electrochemical, optical, and magnetic properties that help to improve their sensitivity, rate of detection, and possible multiple detection abilities (Qu *et al.*, 2013). The PNC-based sensors are designed to be sensitive to the pH changes, possess an affinity to the organic or inorganic contaminants and be able to monitor pathogens (Akhrame *et al.*, 2018).

Conjugated conducting PANI was fabricated onto titania nanoparticles (PANI-TiO_2 NPs) using a microwave-accelerated reaction system to selectively detect 1,2-diaminobenzene (1,2-DAB) in a phosphate buffer phase. The synthesized PANI-TiO_2 NPs

Fig. 4 Common methods used for removal of oil from oil-contaminated seawater. Reproduced from Gatou, M.-A., Lagopati, N., Tsoukleris, D., Pavlatou, E., 2020. Commercial sponges as a novel technology for crude oil removal from seawater and industrial wastewater: A review. *Biomedical Journal of Scientific & Technical Research* 25, 19426–19436.

were deposited on a glassy carbon electrode (GCE) as a thin film using Nafion as the conducting binder. The results indicated that the assembled (1,2-DAB) sensor was able to detect 1,2-DAB in real water samples with high accuracy in a short response time (12 s) (Karim *et al.*, 2020).

Tovide *et al.* fabricated a graphene PANI/tungsten oxide (PANI/WO₃/GR) nanocomposite sensor for the detection of phenanthrene in wastewater. The PNC was synthesized using electropolymerization of a mixture of aniline monomer and tungsten oxide on a graphene-modified glassy carbon electrode (GCE). The assembled sensor showed high phenanthrene detection sensitivity with a dynamic linear range of 1.0–6.0 pM and a detection limit of 0.123 pM which is more than three orders of magnitude lower than the WHO permissible level of 0.2 g/L for polyaromatic hydrocarbons in wastewater. The results also indicated that the sensor exhibited good reproducibility, long-term storage stability, and excellent sensitivity (Tovide *et al.*, 2014).

Devi and Umadevi synthesized a silver–PVA nanocomposite by a chemical reduction method in aqueous media for the detection of heavy metals in wastewater. Their results indicated that the PVA nanocomposite was able to detect the concentration of cadmium in water based on a linear change in surface plasmon resonance absorption strength. On the other hand, the PNC showed good antimicrobial activity against pathogenic bacteria, *E. coli*, and *Pseudomonas aeruginosa* (gram-negative), *Bacillus cereus*, and *Staphylococcus aureus* (gram-positive), which are commonly found in water (Devi and Umadevi, 2014).

In another study, Gutiérrez-Capitán *et al.* fabricated several electrochemical sensors for the rapid analysis of chemical oxygen demand (COD) in urban wastewaters by incorporating CNT-polystyrene composite and different inorganic nanofillers, such as Ni, NiCu alloy, CoO, and CuO/AgO. By comparing the response of the prepared sensors, the CuO/AgO-based nanocomposite sensor showed the best analytical performance for online detection of wastewater COD (Gutiérrez-Capitán *et al.*, 2015).

Other Applications of Polymer Nanocomposites for Wastewater Treatment

In a study conducted by Gatou *et al.* different methods of oil removal from the seawater or oil-contaminated effluents were discussed (Fig. 4). They claimed that commercial sponges such as melamine and polyurethane have attracted great attention in the field of crude oil removal both from seawater and industrial wastewater because of their low cost, low density, excellent mechanical properties, remarkable reusability, and high porous three-dimensional structure. However, the amphipathic nature of the commercial sponges usually limits their application for oil absorption and some modifications should be done to make the surface wettability towards the superhydrophobic/Superoleophilic state (Gatou *et al.*, 2020).

Parsaie *et al.* investigated the oil separation from the oil-contaminated seawater by a modified polyurethane sponge to remove the organic materials and oil from the oil/water systems. A robust superhydrophobic/superoleophilic polyurethane sponge comprising magnesium stearate NPs coating and the phenol-formaldehyde resin was developed by the cost-effective immersion method. The results showed that the optimum contact angle and sliding angle occurred at 175° and 3°, respectively. Regarding the small value of contact angle, the organic absorption time was less than 1 s, covering a wide absorption capacity range of 29–38 g/g depending on the viscosity and density of oils. They proved that the modified polyurethane sponge provided an excellent performance capability of the continuous oil/water separation, required for an industrial application (Parsaie *et al.*, 2020).

Conclusion

Polymer nanocomposites have gained the attention of scientists for water and wastewater treatment applications since they are cost-effective and eco-friendly. In this article, the types of PNCs which are applicable in industrial effluents were first described. Then a detailed explanation was given concerning with their fabrication methods including melting-based methods, solvent-based methods, and in-situ methods, and their industrial applications especially in water and wastewater treatment such as membranes,

adsorbents, photocatalysts, disinfectants, and sensors for monitoring contaminants and removal of all kinds of wastewater contaminants. Although many of the applications for the treatment of industrial effluents highlighted in this article are still in the laboratory stage, some of them have found their way to commercialization such as nanoadsorbents and photocatalysts. However, before the commercialization stage, the uncovered aspects such as the issues of toxicity, recyclability, and recovery should be also considered.

Introduction

The process of adding material layer by layer for fabricating parts from their 3D models (CAD data) is called AM, against the conventional subtractive fabricating processes. The other names for the AM method are 3D printing, RP, and SFF (Parandoush and Lin, 2017). The 3D printing process as a concept was presented in the 1970s with the development of inkjet printing, but the printing of materials instead of ink was introduced in the 1980s with inventing a process called SLA (Horvath, 2014). The SLA process, which Charles Hull invented, allowed manufacturers to fabricate the parts to save production time, money, and energy (de Leon *et al.*, 2016). Fabrication of the 3D components with complicated geometries and high accuracy is essential for AM methods (Vaezi *et al.*, 2013). Besides, the AM methods can be more cost-effective compared to the conventional manufacturing processes (Ngo *et al.*, 2018). Many innovative AM methods have been developed in recent decades, using numerous raw materials for different industries such as biomedical, automotive, aerospace, architectural design, and digital art (Parandoush and Lin, 2017). The most common materials used in the 3D printing industry are polymers because of their low cost, low melting point, low weight, process flexibility, diversity, and ease of adoption to different 3D printing methods (Ngo *et al.*, 2018; Wang *et al.*, 2017). However, 3D printed parts composed of monolithic polymers typically can only be used as conceptual prototypes because of their inferior mechanical properties.

The researches have aimed to resolve the low strength of the 3D printed polymers, which led to the development of numerous methods and materials for manufacturing advanced polymeric composites with improved strength (Wang *et al.*, 2017; Takezawa and Kobashi, 2017). Therefore, the fabrication of polymer matrix composites (PMCs), with superior mechanical performance and proper functionality could be possible by enhancing polymers with particle, fiber, or nanomaterial reinforcements (Wang *et al.*, 2017). PMCs are very attractive materials because of their available simple fabrication processes and low cost. Using monolithic polymers as structural materials are imperfect due to their inferior mechanical characteristics like low strength, elastic modulus, and impact resistance. One possible route for fabricating PMCs is reinforcing polymers by a network of strong fibers (Joseph *et al.*, 2012). The possibility of applying 3D printing of polymers and PMCs has been examined for many years in different industries like aerospace, automotive, biomedical, and electronics (Ngo *et al.*, 2018). Different selections of material types for 3D printing of PMCs has resulted in fabricating light-weight structures with complicated geometries in the aerospace industry (Horn and Harysson, 2012), reduction of material waste, time bottleneck, and setup costs in the electronics (Saengchairat *et al.*, 2017), and printing of organs and tissues in the biomedical industry (Javaid and Haleem, 2018a) (Wang *et al.*, 2017; Joseph *et al.*, 2012). In this article, different AM processes of PMCs, with a reinforced polymeric matrix to attain a fabricated part with superior strength and functionality, are reviewed. Besides, different reinforcing strategies of PMCs for using in 3D printing of customized and complicated geometries and the wide range of AM applications are discussed in detail.

Additive Manufacturing Methods Used for Fabricating PMCs

The available forms of polymers for applying in AM processes are powder, resin, filament, and reactive monomer, which are utilized for 3D printing of monolithic polymers and PMCs (Balla *et al.*, 2019). The most extensively studied AM processes for fabricating PMCs are SLA, SLS, FFF, DIW, and BJ, as shown in Fig. 1.

Stereolithography (SLA)

The SLA was the first marketed 3D printing method invented by Chuck Hull in 1986 (Pahlevanzadeh *et al.*, 2020a). An SLA system consists of a container that keeps photocurable liquid resin, a source of laser (typically UV light) that induces the polymerization

Fig. 1 The most extensively studied AM processes for fabricating PMCs.

Fig. 2 Schematic illustration of SLA configuration. Reproduced from Li, J., Wu, C., Chu, P.K., Gelinsky, M., 2020. 3D printing of hydrogels: Rational design strategies and emerging biomedical applications. *Materials Science and Engineering: R: Reports* 140, 100543.

and cross-linking of liquid resin, a system that allows the horizontal plane (X and Y directions) movement of the laser beam, and a system that controls the vertical plane (z-direction) movement of fabrication platform. The main parts of a SLA system and their configuration to allow for the layer-by-layer AM process is depicted schematically in [Fig. 2](#); ([Li et al., 2020](#)). Irradiation of UV light to the liquid resin surface in a two-dimensional pattern solidifies it through absorbing a single photon to a predefined depth that is usually higher than the step height of the manufacturing platform. Because of that, uncured functional groups on the primary layer after photopolymerization will be polymerized during irradiation for curing the subsequent layer of liquid resin ([Manapat et al., 2017](#)). The manufacturing of the platform goes forward in the Z-direction upon curing layer by layer of resin for creating the solidified 3D construct with a possible resolution of 30 μm ([Mondschein et al., 2017](#)). For promoting mechanical properties, post-processes of curing the manufactured 3D construct with UV light and residual resin washing-off are usually needed because of the possible incomplete reaction of functional groups ([Li et al., 2020](#)).

Selective Laser Sintering (SLS)

The SLS is an AM process that can be used for fabricating complex 3D components by sintering layer by layer of powder material. Sintering of the powder particles is obtained by fusing selected areas of the powder layers made by supplied thermal energy via a laser beam, as illustrated in [Fig. 3](#). A beam deflection system, which can be a Galvano mirror, makes the scanning of the beam on selected areas of each layer based on the corresponding cross-section of the component as extracted from its CAD data. A thin layer

Fig. 3 Schematic overview of the SLS process.

Fig. 4 Schematic illustration of the FFF process. Reproduced from Singh, S., Singh, G., Prakash, C., Ramakrishna, S., 2020. Current status and future directions of fused filament fabrication. *Journal of Manufacturing Processes* 55, 288–306.

of powder, typically with a thickness of 0.1–0.3 mm, is deposited in the building container by a powder deposition system before the laser sintering of that layer (Kruth *et al.*, 2003). As the SLS is a solvent-free process, it has an advantage that offers faster production as compared to the AM processes that need a solvent that requires the printed part to be left for evaporating the solvent (Fina *et al.*, 2017). The polymeric powder materials were the first and are still the most used materials for the SLS process (Kruth *et al.*, 2003). Both amorphous polymers (e.g., polycarbonate) and semi-crystalline polymers (e.g., nylons) have been utilized in the SLS method. Besides, the PMCs could be 3D printed by the SLS process (Kruth *et al.*, 2003).

Fused Filament Fabrication (FFF)

The FFF is one of the most used 3D printing processes with the maximum number of applications in all 3D printing sectors (Singh *et al.*, 2020). Some advantages, such as high flexibilities in the 3D printing process and high cost-effectiveness, have gained the largest share for the FFF process in the 3D printing industry since 2011 (Singh *et al.*, 2020; Brenken *et al.*, 2018). As depicted in Fig. 4 (Singh *et al.*, 2020) schematically, the 3D printers applying FFF technology typically have a thermoplastic filament unrolled from a roll such that the material is pushed toward one or more extrusion nozzles. The material is heated up to its semi-molten condition in the nozzle for preparing the creation of successive layers. The extrusion head can drive both horizontal and vertical paths applying a numerical control mechanism and using a software (Pranzo *et al.*, 2018). The FFF 3D printing process has many other advantages, including the availability of a wide range of nontoxic materials, easily changeable, low machine and maintenance costs, low temperature operating process, and compact 3D printers. Nevertheless, the main disadvantages of the FFF method are imperfect sticking of the material between layers and tool paths, roughness in finishing surface, the requirement of support material in 3D printing, and its removal after 3D printing, and long-time needed for creating the parts with big size (Au *et al.*, 2016).

Fig. 5 Schematic illustration of the FDM process. Reproduced from Carneiro, O.S., Silva, A.F., Gomes, R., 2015. Fused deposition modeling with polypropylene. *Materials & Design* 83, 768–776.

Fused Deposition Modeling (FDM)

The FDM is an AM process, in which a molten thermoplastic material is deposited horizontally, extruded from a nozzle head, manufacturing the part with successive layers. The two most common materials applied in the FDM process are ABS and PLA (Carneiro *et al.*, 2015). Fig. 5 illustrates the FDM process schematically (Carneiro *et al.*, 2015) in order to better understand this method. In this process, a filament is melted at a temperature above its melting point inside the liquefier head and is pushed through the nozzle die by the pressure of still solid upstream filament. With moving the head, the extruded molten polymer is laid down, and the layer is shaped, starting with its perimeters and subsequently filling the inside of the layer (Too *et al.*, 2002). The advantages of the FDM process are high reliability of the process, relatively low initial investment materials cost. The FDM printers could be operated in office environments, with short manufacturing time for the components with thin walls. The process has low material waste that is limited to the supporting structures (Carneiro *et al.*, 2015). The other drawback of the FDM process is that the applied materials in this process have a low melting point, and if the printing objects need support on the overhangs, they will have a rough surface finish, requiring a time-consuming hand-working process for improving surface appearance (Carneiro *et al.*, 2015).

Direct Ink Writing (DIW)

The DIW is a 3D printing process in which a viscous ink as its raw material is extruded from a syringe, applying pneumatic pressure. In this extrusion-based process, different polymers like epoxy and photocurable acrylic resin mixed with reinforcements like silicon carbide whiskers, nylon fibers, and carbon fibers could be printed. The DIW is a user-friendly technology that has been employed efficiently in the biomedical industry for tissue engineering applications (Guvendiren *et al.*, 2016). In the DIW process, the 3D object is printed through the horizontal and vertical movement of the syringe. Fig. 6 shows the process of DIW schematically (Guvendiren *et al.*, 2016), which in this method, at the first step, resin and its curing agent are mixed before loading into the syringe as ink. After extrusion of the ink, it is cured by applying UV induction or thermal heating (Bekas *et al.*, 2019; Lebel *et al.*, 2010). The DIW methods can be divided into two categories of droplet-based approaches and filamentary-based approaches (Seerden *et al.*, 2001; Lewis, 2006). Different designs of ink, including polymer melts, highly shear-thinning colloidal suspensions, waxes, and concentrated polyelectrolyte complexes, have been employed for the DIW process. The method of solidification of mentioned inks could be either through temperature, liquid evaporation, gelation, or solvent-induced phase change (Lewis, 2006).

Binder Jetting (BJ)

The BJ process was developed in the early 1990s at the Massachusetts Institute of Technology (MIT) (Sachs *et al.*, 1990). Fig. 7 depicts a typical process of the BJ technique (Brunello *et al.*, 2016), for the printing of each layer of the object, a layer of powder is spread typically using a counter-rotating roller. Then, the liquid binding agent jets to the powder bed by an inkjet print-head to create the layer's two-dimensional pattern. Heating may be used for helping of curing and moisture control for some binder/powder systems, but it is not a basic requirement for the process (Ziaee and Crane, 2019). After printing each layer, the built platform is lowered to make room for printing the next layer, and the process is repeated. The objects just after 3D printing by the BJ technique are fragile and typically need post processes for improving the mechanical properties (Ziaee and Crane, 2019; Gaytan *et al.*, 2015; Qu, 2020). The key to success in the BJ process is selecting an efficient binder. The binder must be printable and preferably have low viscosity. The low viscosity of the binder allows forming the stream of individual droplet beads and

Fig. 6 Illustration of DIW process. Reproduced from Guvendiren, M., Molde, J., Soares, R.M., Kohn, J., 2016. Designing biomaterials for 3D printing. *ACS Biomaterials Science & Engineering* 2 (10), 1679–1693.

Fig. 7 Schematic illustration of BJ process. Reproduced from Brunello, G., Sivoletta, S., Meneghello, R., *et al.*, 2016. Powder-based 3D printing for bone tissue engineering. *Biotechnology Advances* 34 (5), 740–753.

subsequently rapidly breaking off from the nozzles (Ziaee and Crane, 2019). The primary particle bonding techniques generally are categorized as In-Liquid and In-Bed binding. In the In-Liquid binding, the binder is completely carried by jetted liquid while in the In-Bed binding; a rheologically simple liquid is printed and interacts with dry glue particles embedded in the powder bed. The interparticle bonds are initiated upon hydration (Utela *et al.*, 2008). The In-Liquid solutions cause more premature failure of print-head than the In-Bed mechanism because of the drying of the glue agent in the nozzles but offer a wider range of power systems (De Gans *et al.*, 2004). Commonly used In-Liquid binders that contain organic cross-linking agent (Ziaee and Crane, 2019) are butyral resins (Ziaee and Crane, 2019), polyvinyl (Ziaee and Crane, 2019), polysiloxanes (Reis *et al.*, 2005), PAA (Moon *et al.*, 2002) and acrysol (Yoo *et al.*, 1993). They typically decompose thermally during post-processing and leave little residue. Photo-curing polymers can be used for reducing challenges in binder migration after printing (Ziaee and Crane, 2019).

Polymer Matrix Composites (Natural Based or Synthetic Based)

Polymeric materials in the liquid state or the low melting temperature are extensively applied in the 3D printing industry because of their light-weight, low cost, and high flexibility in the process. These 3D printed polymeric products suffer from inferior mechanical properties and functionality as a big challenge for their extensive applications (Wang *et al.*, 2017). The composite materials consist of two or more phases that are different in chemical and physical specifications and are separated by an interface. The composites have a matrix phase, and the other phase or phases are dispersed in the matrix, and the bulk properties of the

Fig. 8 Advantages and disadvantages of polymer matrix composites (PMCs).

composites are remarkably different from those of any of the composite ingredients (Joseph *et al.*, 2012). Based on the matrix type, which could be metal, ceramic, or polymer, the composites are categorized into MMCs, CMCs, and PMCs, respectively (Avila *et al.*, 2003 and Balla *et al.*, 2019) in this chapter, we have focused on the PMCs, which have many advantages against very few drawbacks as presented in Fig. 8. PMCs that are reinforced with different materials in the form of fibers (short and continuous) and particles (in the size of micro or nano) have been successfully manufactured by AM techniques, which will be described in detail in the following subsections.

3D Printing of the Fiber-Reinforced PMCs

The fiber reinforcements can remarkably improve the properties of polymeric matrix materials. Fibers-reinforced PMCs are vital materials with various applications because of their specifications, like high specific strength, acceptable corrosion behavior, and rigidity (Saroia *et al.*, 2020). The 3D printing processes commonly used for producing fiber-reinforced PMCs are FDM and DIW technologies (Wang *et al.*, 2017). The fiber-reinforced PMCs have different applications in the automotive, aerospace, and biomedical industries due to their high chemical resistance and good mechanical properties. Carbon fibers and glass fibers are commonly used for reinforcing the polymeric matrixes in the PMCs used in AM processes (Wu *et al.*, 2020; Ning *et al.*, 2015; De Mori *et al.*, 2018; Markstedt *et al.*, 2015). While the PMCs reinforced with short or chopped fibers are easier for processing, the PMCs reinforced with continuous fibers usually display comparatively superior tensile properties in the printing direction (De Mori *et al.*, 2018).

Table 1 represents the results of several pieces of research relating to the fiber-reinforced PMCs and their effects on the produced PMCs. For instance, Markstedt *et al.* (2015) improved the compressive modulus of alginate (75–250 kPa) by reinforcing it with cellulose nanofibers. Based on the results, the 3D printed scaffolds supported the cultured human chondrocytes, in which 73%–86% of viability was observed after one and seven days. The same bio-ink composition, consisting of cellulose nanofibers in the alginate matrix, combined with human chondrocytes and mesenchymal stromal cells, were found for promoting in vivo chondrogenesis after subcutaneous implantation of the 3D printed constructs in mice. The research results presented the potential capability of 3D bio-printing of human cartilage for the clinical applications (Apelgren *et al.*, 2017). In another research, Carneiro *et al.* (2015) used glass fiber reinforced PP composite for fabricating 3D printed parts applying the FDM process. Their investigations showed that the tensile strength and modulus enhanced by 40% and 30%, respectively, compared with the monolithic PP. Besides, they showed that 0° printing orientation has better mechanical properties compared to 45°, crossed 45° ($\pm 45^\circ$), and 90° printing orientations, in the same conditions (Carneiro *et al.*, 2015). The fibers orientation is one of the main parameters that influence the efficiency of fibers in the enhancement of the polymeric matrix. For investigating the effect of fibers orientation, Compton and Lewis. performed some experiments applying the DIW process (Compton and Lewis, 2014). For the preparation of the ink, they added both SiC whiskers and carbon fibers to the reinforced epoxy resin as a cellular matrix composite. These bio-inspired wood structures were fabricated with precise design parameters. In the 3D printed objects, high stiffness and toughness were seen as they maintained the orientation and alignment of fiber and whiskers (Compton and Lewis, 2014).

The other important parameter that influences the mechanical properties of 3D printed fiber-reinforced PMC is the fiber content. Ning *et al.* (2015) presented that the fiber content has a remarkable effect on the mechanical characteristics of carbon fiber

reinforced ABS composite 3D printed with FDM technology. The researchers showed that an increment of fiber content up to some limit would improve the mechanical properties of the printed composite, but further content of fiber would have a reverse influence on the properties because of the porosity increasing on the part. The outcomes revealed that with up to 5 wt% of fiber concentration, the best mechanical properties were obtained rather than higher content. As mentioned before, continuous fibers have a higher effect on the improvement of mechanical properties of PMCs compared to the short fibers as the continuous fibers can be oriented in the 3D printing direction. Regarding this issue, Li *et al.* evaluated continuous fiber-reinforced PLA composite, 3D printed by the FDM process (Li *et al.*, 2016). Their outcomes showed that the improvement in tensile and flexural strengths in continuous fiber-reinforced specimens was 13.8% and 164% higher than the short fibers reinforced PMCs, respectively (Li *et al.*, 2016). Nevertheless, 3D printing of continuous fiber-reinforced PMCs is challenging, and researchers are trying to develop an appropriate and standard paradigm for it (Saroia *et al.*, 2020).

3D Printing of Particle Reinforced PMCs

The particle reinforcements have been widely used to enhance the properties of the polymeric matrixes because of their low cost. Particles can be easily mixed with polymers, in all forms of powder, for use in the SLS process, liquid for use in the SLA process, and also could be extruded into printable filaments for use in FDM (Wang *et al.*, 2017). Commercialization and real-world applications of the polymers are addressed and resolved with the development of PMCs. Lately, Hwang *et al.* (2015) utilized the FDM process to investigate the thermo-mechanical properties of metal reinforced PMCs. They used copper and iron particles with an average size of fewer than 24 and 43 μm , respectively. The metallic particulate reinforcements with different concentrations from 10% to 80% were used for observing the influences on the properties of the 3D printed composite. Raising the temperature during extrusion from 190°C to 220°C increased the tensile strength while the viscosity was reduced. Besides, the ductility was increased with raising the reinforcement content but commenced to decline when the filler content exceeded a particular amount (Chung, 2001).

The existence of the particulate reinforcements in the polymeric matrix can improve the physical, chemical, and mechanical properties of the matrix. Besides, the presence of reinforcement particles can solve some difficulties encountered during the printing process. One of the key issues of the printing process is loose bonding between the layers because of high thermal expansion in monolithic polymers. The incorporation of metallic particles can decrease the thermal expansion of the resulted composite and helps for the better bonding of the layers (Chung, 2001).

3D printing of cell-laden scaffolds applying various hydrogel compositions (e.g., alginate, chitosan, and gelatin), reinforced with HAP particles, have been investigated (Kesti *et al.*, 2015; Wenz *et al.*, 2017). The results have been shown that the addition of

HAp particles can remarkably improve the mechanical characteristics of the hydrogels and promote osteogenic differentiation *in vivo*, making them appropriate for repairing bone tissue defects (Wenz *et al.*, 2017; Bendtsen *et al.*, 2017).

Nikzad *et al.* (2011) studied the influence of reinforcing the ABS matrix with copper and iron particles. The outcomes showed that the presence of the iron particles decreased the tensile strength of ABS and the resulted composite was harder and more brittle than the matrix. Masood and Song *et al.* developed a metallic powder reinforce PMC by incorporating iron particles in different sizes ranging from less than 30 to 80 μm in the P301 nylon matrix (Masood and Song, 2004). The resulted composite was found appropriate for direct rapid tooling applications. It was also found that the reinforcements with larger particle sizes can decline the mechanical properties of the 3D printed object. In other words, it revealed that the particulate reinforcements with smaller particle sizes could better enhance the properties of the polymeric matrix. In the next subsections, the usage of nanomaterials for the improvement of PMCs properties will be discussed.

3D Printing of PMCs Reinforced by Nanomaterials

Recent advances in nanoscience and nanotechnology have facilitated the development of nanocomposites with excellent mechanical and thermal properties at a remarkably lower weight. A composite is called nanocomposite when one of the reinforcement dimensions would be less than 100 nm (Francis and Jain, 2015). The polymer-based nanocomposites could be processed the same way as pure polymers without considering the machine for use in AM. Different types of polymer-based nanocomposites using different nanosized reinforcements have been developed for AM applications (Wu *et al.*, 2020). Nanomaterials like CNTs (Yan *et al.*, 2016; Pahlevanzadeh *et al.*, 2019b), graphene (Gray *et al.*, 1998), graphite (Sengupta *et al.*, 2011), ceramic (Pahlevanzadeh *et al.*, 2019a, 2018) and metallic nanoparticles (Zhang *et al.*, 2006) have exhibited excellent mechanical, electrical and thermal properties. Thus, the incorporation of nanomaterials into polymers for 3D printing could allow the fabrication of high-performance functional nanocomposites. Nanomaterials have been applied for enhancing the mechanical characteristics of 3D printed polymer-based components (Wang *et al.*, 2017). In addition, for improving the mechanical properties of PMCs, graphene-based materials can influence the cellular behavior of composites and induce cell proliferation and stem cell differentiation. Some nanomaterials added to polymers for the fabrication of appropriate PMCs for use in AM processes and their effect on the resulting nanocomposites are listed in Table 2. For example, Huang *et al.* (2017) investigated the incorporation of low concentration (up to 25 ppm) of graphene nanomaterials to the PU matrix. The results showed that the addition of nanosized graphene has significantly enhanced the oxygen metabolism and neural differentiation of NSCs. Besides, the samples containing 25 ppm graphene exhibited higher gene expression results than those in 10 ppm graphene reinforced (Huang *et al.*, 2017). In another research, Wei *et al.* (2015) tried to improve the electrical conductance of ABS material by incorporation of nanosized graphene applying the FDM process. The results showed that by incorporating 5.6 wt% of homogeneously distributed graphene, electrical conductivity could be improved up to four times (Wei *et al.*, 2015). The mechanical properties of 3D printed specimens are strongly dependent on the printing orientation (Wu *et al.*, 2020; Yamamoto *et al.*, 2019). The filament uniformity is another crucial parameter for achieving the high quality of the printed part. The incorporation of small contents of nanofiller can remarkably change the rheological behavior of the polymer, which is vital in the filament extrusion process (Yamamoto *et al.*, 2019). Also, the homogenous dispersion of the nanoparticles is significant for achieving the highest possible properties. Nanoparticles can remarkably affect the rheology of the polymer in the molten state and is a dominant factor influencing the printability (Wu *et al.*, 2020; Zheng *et al.*, 2006). On the other hand, during the manufacture of PMCs, the problems associated with agglomeration and poor interfacial bondage of nanoparticles with polymers could be faced. Chemical or thermal surface treatment can overcome these challenges (Saroia *et al.*, 2020). In a research conducted by Zheng *et al.* (2006) the reinforced and non-reinforced specimens of polystyrene were evaluated, and enhancements in reinforced samples were reported especially increasing of about 300% in tensile strength compared to the non-reinforced samples. Chizari *et al.* (2016) fabricated a type of 3D printed conductive material by blending CNTs and PLA in the ball mill. Various contents of CNTs were mixed with PLA to evaluate the effect of the reinforcement concentration on conductivity. The results showed that with increasing CNTs concentration, the conductivity of the resulted composite was improved, but the clogging of the nozzle was also observed. Dichloromethane was used as a solvent for dissolving dried forms of CNTs and PLA uniformly and printed through the 3D printing process. The electrical conductivity of fabricated specimens was higher than the other conductive 3D printed PMCs (Chizari *et al.*, 2016). With the help of nanotechnology, AM is used in different applications, which have been described in the following sections.

Applications of Additively Manufactured PMCs

Medical Applications

Recently, 3D printing in tissue engineering applications, including medical devices and scaffolds, regenerative medicine, ex-vivo tissues, and drug delivery, have attracted intense attention (Singh and Ramakrishna, 2017). Various applied PMCs with their relevant AM processes that have been used in biomedical applications are summarized in Table 3.

For scaffolds, providing cell infiltration and proliferation is a vital requirement for physical connection. Conventional manufacturing methods have the poor ability to incorporate internal architecture and controlling the porosity of the scaffold. Applying AM processes can solve these issues by their capability to control the pore size and pore distribution in the fabricated scaffold

Table 2 Summary of the results for polymer matrix composites (PMCs) reinforced by nanomaterials fabricated by various methods including 3D printing

<i>Polymeric matrix</i>	<i>Reinforcement nanomaterial</i>	<i>Fabrication method</i>	<i>Results</i>	<i>References</i>
Ethylene/1-octene copolymers (EOCs)	CNT	Hot pressing	Increasing thermal conductivity	Yan et al. (2016)
PMMA-Mon	CNT	Casting	Suitable mechanical properties and supporting osteoblast cells	Pahlevanzadeh et al. (2019b)
Polypropylene (PP) strands	Liquid crystalline polymer (TLCP) fibrils	FDM	Revealing that monofilaments tensile properties is dependent on diameter of capillary	Gray et al. (1998) , Sengupta et al. (2011)
PMMA-PCL	Baghdadite	Casting	Great mechanical properties, and favorable cytocompatibility	Pahlevanzadeh et al. (2019a)
PMMA-PCL	Fluorapatite	Casting	Proper mechanical properties, favorable bioactivity and high MG63 cells viability	Pahlevanzadeh et al. (2018)
Epoxy resin	Carbon-coated nickel nanoparticles	Using electrostatic generator and molding	Dielectric constant increasing	Zhang et al. (2006)
Polyurethane	GNPs	Bioprinting	Increased the oxygen metabolism (2–4 times more) and enhancement of neural differentiation	Huang et al. (2017)
ABS	GNPs	Extrusion based printer	Demonstrating a printable form of graphene composite containing up to 5.6 wt% graphene for the first time	Wei et al. (2015)
Polystyrene	Nano- Al_2O_3	SLS	Increasing the notched impact strength and tensile strength	Zheng et al. (2006)
PLA	CNT	Extrusion based printer	Suitable construct for different applications like various types of sensors	Chizari et al. (2016)
PLA	CNT	Direct writing	Excellent sensitivity	Guo et al. (2015)
PLA	Silver nanowire	FDM	Indicate high antibacterial effect against both <i>Staphylococcus aureus</i> and <i>Escherichia coli</i>	Bayraktar et al. (2019)
PLA	Clay	FDM	Increase storage modulus and thermal stability	Coppola et al. (2018)
PLA	GNPs	FDM	Enhance the tensile and flexural strength and suitable biocompatibility	Wang et al. (2020)
PLA	CNT	Solvent-cast 3D printing	Functional optimization of light-weight and semi-transparent EMI shields	Chizari et al. (2017)
PLA	Graphene	FDM	Enhance the mechanical and thermomechanical properties	Prashantha and Roger (2017)
PLA/PU	GO	FDM	Improved the mechanical property, thermal stability and indicating good biocompatibility	Chen et al. (2017)
Epoxy acrylate	TiO ₂	SLA	Introduce a low-cost method to improve the performance of the photosensitive resin	Yugang et al. (2011)
ABS	Graphene	FDM	A graphene composite, with a graphene (up to 5.6 wt%), can be 3D printable into CAD for the first time	Wei et al. (2015)
Polystyrene	Al_2O_3	SLS	Provides a theoretical and technical basis for the production of nano- Al_2O_3 / polystyrene products	Zheng et al. (2006)

Fig. 9 Schematic illustration of different development steps of tissue engineering scaffolds including: (a) data acquisition by the medical imaging techniques; (b, c) processing the derived data by CAD and CAM software and designing the customized scaffold; (d) AM manufacturing of the scaffold; (e, f) cell seeding and culturing; (g) implantation of the AM fabricated scaffold; (h) tissue regeneration.

(Kumar and Kruth, 2010). Tissue engineering aims to develop the temporary 3D components for applying to promote the process of natural healing of damaged tissues. The natural polymers and their composites, as one of the biomaterial categories, have been broadly investigated due to their capability to reproduce the perfect 3D extracellular environment for the growth of the tissue. The 3D components with a customized designed geometry with different sizes and shapes and having a fully interconnected network of pores could be fabricated by AM methods. CAD data for the development of scaffolds could be derived from diagnostic medical images, like CT and MRI, typically treated by CAD and CAM software. The process of AM manufacturing of tissue engineering scaffolds has been illustrated in Fig. 9. The bio-inks that are applied in bio-printing have an influential role in fabricating regenerative medicine (Mota *et al.*, 2015). The 3D bioprinting is known as an AM process that can be applied for manufacturing the customized structures for using to repair the damaged tissues or organs (Huang *et al.*, 2017 and Bishop *et al.*, 2017). Fig. 10 represents bio-printing process overview in order to better understanding how to combine the 3D printing method for a polymeric matrix with live cells.

The 3D printed PMCs have been mostly used in the field of hard tissue regeneration. For example, Dorj *et al.* (2012) reinforced the chitosan matrix with a bioglass bioactive reinforcement agent for the robocasting 3D printing process. Their outcomes revealed that the composite scaffold containing 10 wt% nano bioactive glass presented a bimodal structure, including macro and micro-structures. In their process, the solution of the composite was rapidly solidified when the samples were placed into a dry-ice tank. The manufactured chitosan/10 wt% nano bio-glass scaffold showed high bioactivity and good cell attachment properties. In another research, Caballero *et al.* (2019) reinforced chitosan with suspensions of Ca-P particles in acidic aqueous solution in the robocasting process for fabricating chitosan/Ca-P scaffolds. The study results revealed that rheological properties of combination might be adjusted by changing the composition in which more printable inks were achieved with higher amounts of chitosan.

3D printed PMCs have been successfully used in soft tissue engineering and drug/growth factor delivery. Xiong *et al.* (2017) presented the AM fabricated gelatin-sulfonated silk composite scaffold, incorporated with basic fibroblast growth factor 2 (FGF-2) via binding with a sulfonic acid group (SO₃) (3DG-SF-SO₃-FGF). Modified silk fibroin with sulfonated moieties was applied in the scaffold to improve its hydrophilicity and facilitate the incorporation of FGF-2. They showed that the immobilized growth factor FGF-2 can exhibit sustained release kinetics and can stimulate *in vitro* cell proliferation and migration. The AM fabricated scaffold displayed promising results when applied to treat full-thickness cutaneous injuries in an animal model. The outcomes showed that the incorporation of FGF-2 in the scaffold improved the rate of proliferation from about 40% to approximately 75%, tissue morphology, collagen fibril assembly, blood vessel formation, and expression of different corresponding markers.

Fig. 10 Process chart of bio-printing.

Orthopedics is one of the well-known fields in which 3D printed PMCs are applied (Choi and Kim, 2015; Haleem *et al.*, 2018; Leigh *et al.*, 2012). The AM technology is used for fabricating anatomic models, surgical instruments, tool design, splints, implants, and prosthesis using various types of materials like nylons, polymers, and even metals. In orthopedics, the customized analysis of the patient, using medical images, is vital for obtaining precise data (Javaid and Haleem, 2018a; Cooperstein *et al.*, 2015).

Besides, 3D printing has the potential to help the cardiologists and cardiac surgeons. The 3D model of the customized heart for a specific patient could be fabricated by AM in a short time and with a comparatively low cost. In this way, before performing the actual surgery on the patient, the 3D model is created and analyzed. This process could improve the treatment results of the patients and saving their lives (Haleem *et al.*, 2018). The materials that could be used for 3D printing of the components of the artificial heart are plastic, powder, metal, and composites (Haleem *et al.*, 2018).

Electronics Applications

The electronic components or devices that have the ability to control and amplify the electric charges are called active electronic components (Saengchairat *et al.*, 2017). Different subtractive traditional manufacturing processes have been broadly used for fabricating active electronic components typically based on photolithography, which has many drawbacks, including complicated and expensive setup, hazardous chemical preparation, and a significant wastage quantity of rare-earth material (Saengchairat *et al.*, 2017). The AM techniques, which have apparent advantages comparing with the traditional processes like decreasing in material wastage, less fabrication time, and lower setup cost, can solve the mentioned disadvantages. Lately, many studies have been conducted on the 3D printing of various electronic sensors. Leigh *et al.* manufactured different sensors, including piezoresistive and capacitive types, applying the FDM process utilizing carbon black reinforced PCL composite (Leigh *et al.*, 2012). The piezoresistive sensors showed their ability to detect the mechanical flexing based on the variation of the electrical resistance. In the same way, the capacitive sensors that were 3D printed on the customized fabricated devices like 3D smart vessels, which can sense the presence of water based on the changes of capacitance (Leigh *et al.*, 2012).

In recent years, some studies have tried to fabricate the 3D printed, electronic components. A connector for an electrical circuit was 3D printed, applying a digital light process using the material of silver and cross-linked photopolymer (Cooperstein *et al.*, 2015). The fabricated 3D porous structure utilizing the printable oil-in-water emulsion was dipped in a dispersion of silver nanoparticles, then sintered to attain conductive percolation paths. The porosity and total surface area of the 3D printed part could be controlled by changing the parameters of the process. Therefore, the electrical conductivity could be potentially designed.

Some studies have also tried to 3D print the electronic components by encapsulating the metallic wires into a polymeric matrix. This method of 3D printing is similar to the utilized method for fabricating continuous fiber-reinforced PMCs. Molten styrene block copolymers and Cu wires were individually supplied and co-extruded. The printed two-phase composites were confirmed to be used as an open membrane switch (Saari *et al.*, 2015), which is activated when the membrane is deformed by pressure contact, resulting in the Cu wires on adjacent polymer layers to be shorted together.

The other application of AM in electronics is fabricating the supercapacitors. Tanwilaisiri *et al.* (2018) tried to fabricate a novel multi-material electrochemical supercapacitors using a combined AM manufacturing process, including FDM and DIW. The results of the research showed that the fabrication process has an outstanding perspective on the manufacturing of other 3D printed electrochemical devices (Tanwilaisiri *et al.*, 2018). The concept of green energy, because of its advantages, including cost-effectiveness and pollution-free aspects, has attracted the attention of many researchers. AM technology has various applications in the field of green energy. As a self-powered electronics component, TENG is a unique and practical usage of green energy. Qiao *et al.* (2018) applied the FDM process for fabricating a type of TENG, which could generate green energy from the vibrations in environmental conditions. They investigated different factors, including input power, excitation frequencies, and current zigzag

patterns, which had a direct or indirect effect on the efficiency of TENG. The efficiency of their designed TENG in the mode of vertical contact separation was documented up to about 64% (Qiao *et al.*, 2018).

Aerospace Applications

The AM technology has been accepted in the aerospace industry due to many advantages that are described below. Firstly, the potential to a remarkable reduction of “buy to fly ratio”, which is defined as the ratio of the mass of required material for fabricating a component to the final mass of the component that flies on the airplane. This ratio could be as high as 20:1 for some aerospace components fabricated by conventional manufacturing processes. For the AM fabricated parts, this ratio is approximately one. The effective usage of the material is often an essential concern for numerous aerospace applications (Horn and Harrysson, 2012). Many research organizations are discovering the possible routes to use the AM technology to fabricate PMCs that can be used in aerospace applications because of the likely cost-effectiveness resulting in reducing fuel consumption (Wang *et al.*, 2017). SLS and EBM methods can make the fabrication process more comfortable and more cost-effective. Secondly, the capability of using carbon fiber reinforced PMCs for fabricating the high precision and geometrically complicated airfoils, blades, propellers, etc (Saroia *et al.*, 2020; Invernizzi *et al.*, 2016). The AM fabricated metallic alloys have been applied for many parts in the aerospace industry, such as turbine blades and engine exhaust because metals have higher strength for sustaining at elevated temperatures than the plastics (Goh *et al.*, 2017).

Nevertheless, the plastics could also be an alternative option for the AM fabrication of propellers and wind turbine blades due to their lower weight and more cost-effectiveness than the metals. Some polymers have been developed in recent years that can resist high temperatures, which can be applied in many aerospace applications. A plastic material containing chopped carbon fiber and a type of thermoplastic heat-resistant polyetherimide polymer has been developed, which can resist the temperatures up to about 205°C and can be used for fabricating the inlet guide vanes using the FDM process (Misra *et al.*, 2015).

The AM has been proved as an innovative technology in the aerospace industry. Many companies that manufacture airplanes are using 3D printing methods to reduce the weight and manufacturing time of different functional parts. The PBF method, as an AM process, offers the fabrication of the small parts with high accuracy. The PBF method has the potential to give a high degree of freedom to the manufacturer for design optimization and its functional attributes. The brackets of Airbus A350 XMB were fabricated using the PBF process. The manufactured parts had a 30% lower weight, and the manufacturing time was also reduced up to 75%, compared with the conventional fabrication processes (Wang *et al.*, 2017).

Benefits, Limitations, and Future Trends

In recent years, various AM techniques using different material types, including thermoplastic polymers, metals, and ceramics matrix, reinforced with many reinforcements such as metallic nanoparticles, fibers, and various conductive materials, which can improve their functionality, have been applied. Choosing the material depends on the applied AM technology and the properties needed for the product (Saroia *et al.*, 2020).

Despite the enhancement that can be achieved by using nanoparticles for reinforcing in composites, they may decline the formability of the fabricated nanocomposites (Weng *et al.*, 2016; Coppola *et al.*, 2017). Decreasing in ductility could be attributed to two main reasons: (1) inadequate interfacial bonding of the reinforcement and matrix, and (2) clustering of nanoparticles, which can act as stress concentrating defects (De Mori *et al.*, 2018). Besides, the loading of reinforcements is limited to a specific quantity that is called the threshold point. For the amounts higher than that point, the reinforcement particles start to agglomerate and form the voids, resulting in declining mechanical properties (Saroia *et al.*, 2020). Chemical or thermal surface treatments (Zheng *et al.*, 2006; Kim *et al.*, 2013) could be applied before printing to solve these issues. AM techniques are applied in many industries in different ways. The aerospace and automotive industries allow manufacturing the lightweight components with complicated geometries such as honeycomb cell and the parts containing cavities and angle cuttings for decreasing the specific strength. Besides, educational models for studying the physical concepts and visualization could be developed by 3D printing. The other field that can extensively use 3D printed components is biomedical because of the ability of AM methods for accurate adjustment of porosity shape and size, fiber size, appropriate interconnectivity of the pores, and fabrication of customized components for the patients. For instance, different advantages have been caused by using the 3D printing process to fabricate the heart components in cardiology applications. For describing the process to the patient, the anatomical 3D model is also useful for better understanding. Besides, the 3D printed model can be used for training prior to surgery, increasing the possibility of saving lives, improving results, and offering new treatments (Haleem *et al.*, 2018).

Despite remarkable improvements of PMCs additive manufacturing in recent years because of facilitating the customized production of strong, lightweight products which allows designs that were not possible with conventional fabricating processes, it is still not widely accepted by most industries. There are many drawbacks to AM technology that should be solved. For instance, the wide application of 3D printing is strictly limited by printable materials. Although reinforcements can enhance the performance of 3D printed PMCs, compared to the PMCs fabricated by conventional methods using molding, most of the printed composites still have lower mechanical properties and are not able to meet the functional requirement (Wang *et al.*, 2017). The other problem is that, in many cases, the fabrication cost of the parts using AM processes is much more than that of conventional processes (Thomas and

Gilbert, 2014), as the most AM processes are time-consuming now, and fabricating the parts with large size is difficult (De Mori *et al.*, 2018). Besides, the implants that fabricated by need high cost for design. The other problem of AM technology is the required time for preparing the physical model. It depends on the level of complexity and size of the model. The acquisition and processing of data based on the images take a long time. Then for the fabrication of the model, it depends on the types of technologies of AM. In some cases, it is not implemented and can only be used to better understand the actual surgery (Javaid and Haleem, 2018b). Normally, the fabrication of scaffolds that successfully mimic the structural and mechanical characteristics of the target tissue is a complicated process. On the other hand, monolithic polymers do not show good mechanical properties, especially in hard tissue engineering applications (De Mori *et al.*, 2018). So it seems that AM made PMCs are promising materials for tissue engineering and regenerative medicine because of their adjustable properties (Joseph *et al.*, 2012; De Mori *et al.*, 2018). Since all kinds of cells require a network of vessels to gain access to nutrients and oxygen and expel unwanted products, vascularization is a vital matter. For that reason, the formation of a complete complex vascularization network in PMCs printed-specimens for fabricating full organ is remaining a secret (Mironov *et al.*, 2009).

Lastly, it should be mentioned that most of the challenges in AM technology are dependent on the process. For example, choosing the best binder in 3D printing is considered one of the difficulties in the BJ process (Sahranavard *et al.*, 2020). As previously stated, further studies on chemical or thermal surface treatment are required to fabricate the PMCs with a uniform dispersion of reinforcements and, consequently, adequate mechanical properties. Generally, enhancing the mechanical properties of the PMCs could be attained through uniform distribution of fiber, particle, or nanomaterial reinforcements in the polymeric matrix for tissue engineering and wound healing applications (Hadisi *et al.*, 2020; Bakhsheshi-Rad *et al.*, 2017, 2019, 2020; Parham *et al.*, 2020; Pahlevanzadeh *et al.*, 2020b). Also, the reduction in cost and fabrication time in AM processes may result in using the AM in the production of the parts with large size.

Conclusion

The AM technology has a remarkable impact on the modern world, and despite many challenges and disadvantages, its applications have been increased with various potentials, especially for fabricating polymer matrix composites (PMCs) due to their adjustable and excellent properties such as high specific strength, good resistance against corrosion, abrasion, impact, fatigue, and fracture. As discussed in this chapter, many signs of progress have been made in developing 3D printing of PMCs, including improving properties and their applications in aerospace, electronics, and biomedical industries. It is worth noting that some remarkable problems such as agglomeration of reinforcement, the formation of voids, time-consuming, and low mechanical properties should be solved in 3D printed PMCs. Finally, some advantages and disadvantages were pointed out for supplementary studies on 3D printed PMCs.

New Design Consideration of Polymer Matrix Composite Materials

Peng Liu, Lanzhou University, Lanzhou, China

Introduction

In the last decades, the polymer matrix composite materials have attracted more and more interests in various potential applications, by improving the mechanical and thermal property by introducing the inorganic nanomaterials as reinforcement agents, or providing special functions (such as magnetic, electrical or electrochemical property) with functional inorganic nanomaterials. The physical blending approach is the most used method to prepare the polymer matrix composite materials, also the simplest one, in which the fillers were surface modified with small organic molecules to reduce surface polarity or improve the interfacial property between the polymeric matrices. For the inorganic nanomaterials, which show nanoscale size and strong surface polarity, they might transfer through the polymeric matrices and form aggregates in service (Fig. 1), especially for the applications at a high temperature near to the glass transition temperature (T_g) of the polymeric matrices (Colonna *et al.*, 2014).

In fact, besides the annealing treatment (Liu *et al.*, 2015b) and the thermal conduction application or those at elevated temperatures (Lewin *et al.*, 2006), it usually produces heat in some applications, such as periodic bending, shocking or vibration (Shabaniverki *et al.*, 2018), electric conduction (Ren *et al.*, 2018), tribology (Massod *et al.*, 2017; Zhao *et al.*, 2016), irradiation (Asadinezhad *et al.*, 2013; Patel *et al.*, 2006) and so on. In such cases, the temperature will rise because of the transformation of the impact energy, electric energy, mechanical energy or radiant energy into heat energy. The flame-retardant performance could be enhanced by the migration of the clay mineral or SiO_2 particles to surface of nanocomposites, which reinforce the intumescent char (Kiliaris and Papaspyrides, 2010; Laoutid *et al.*, 2009; Zhang *et al.*, 2017). It has been paid much attention for the safety in the food packaging application (Bandyopadhyay and Ray, 2019; Farhoodi, 2016).

The miscibility and migration of the inorganic nanomaterials in the polymeric matrices has been rarely involved in most of the reported works except for the food packaging application, because that the structure and performance of the as-prepared composites were usually analyzed, but not in service or after service. However, the phenomenon would lead to poor stability of material properties. The question is usually of no great importance in the crystalline polymer matrices, because that the inorganic nanomaterials could be inlaid in the continuous phase formed by the polymer crystals. The migration of the inorganic nanomaterials could not be avoided even in the hydrogels and vulcanized rubbers with low crosslinking degree.

In recent years, the polymer matrix nanocomposite materials have been designed with the functionalized inorganic nanomaterials as crosslinking agents. In the designed structure, the inorganic nanomaterials were introduced into the 3-D covalently crosslinked networks in the resultant nanocomposite materials. Therefore, the migration of the inorganic nanomaterials could be efficiently avoided, and the stable miscibility of the inorganic nanomaterials could be achieved in the advanced composite materials. Such 3-D covalently crosslinked networks could be easily prepared via the in-situ polymerization in presence of the functionalized inorganic nanomaterials (Liu *et al.*, 2014d; Zhu *et al.*, 2016a) or the surface modification (Pan and Liu, 2018), which showed negative effect on the processing and molding of the resultant nanocomposite materials. For ease of processing and application, the advanced composite materials with inorganic nanomaterials in their 3-D covalently crosslinked networks were usually synthesized with a one-step for direct application, or two-step method in which the crosslinked networks were formed with the functionalized inorganic nanomaterials during the processing and molding (Bakir *et al.*, 2020). In the present article, the design and application progress in the advanced composite materials is reviewed, classified in their applications, with emphasis on the structure-performance relationship. Additionally, the future development direction of this field was also prospected in the last.

General Research

The 3-D covalently crosslinked networks have been widely fabricated via the crosslinking during molding approach, with the inorganic nanomaterials as crosslinkers (Fig. 2), mainly the carbon nanomaterials and SiO_x nanoparticles, respectively.

Fig. 1 Aggregation of the inorganic nanomaterials in the polymeric matrix via migration.

Fig. 2 Crosslinking of polymer matrices with multifunctional inorganic nanomaterials with the end groups or side groups in polymer chains.

Carbon Nanomaterials

Carbon nanomaterials, such as carbon nanotubes (CNTs) and graphene, have been widely used in polymer matrix nanocomposite materials, because of their excellent mechanical strength, as well as high thermal and electrical conductivity. They were usually used after exfoliation, in which they were oxidized to improve their aqueous dispersibility. During the oxidization, oxygen-containing functional groups could be introduced, facilitating the application as multifunctional crosslinkers.

Carbon nanotubes

The carboxyl groups in the oxidized CNTs could act directly the functional groups for the crosslinking. For example, mechanically robust single-walled carbon nanotubes (SWCNTs)/poly(allylamine) composites were designed by crosslinking the polymer with carboxylic acid functionalised SWCNTs (Satti *et al.*, 2010). The ultimate tensile strength and Young's modulus of the crosslinked buckypaper films were 42 MPa and 11 GPa respectively, more than 9 times higher than the one for noncrosslinked PAH infiltrated buckypaper films.

Besides, the amino functionalised CNTs could be synthesized by the functional group conversion reaction for other polymer matrices (Fan *et al.*, 2018; Zhu *et al.*, 2019). Similar as the above buckypaper films, the crosslinked aerogels were obtained in the two works, because of the release of small molecules in the condensation.

Additionally, the multiwalled carbon nanotubes (MWCNTs) were functionalized with epoxy prepolymer to introduce epoxy groups. Then they were used as crosslinker for the waterborne polyurethane (WPU) (Wang *et al.*, 2020). The composite films were formed by the reaction of the epoxy groups in MWCNTs and the carboxyl or amino groups in the WPU chains, showing a significant improvement in the mechanical property, thermal stability, water resistance, and electrical conductivity.

Graphene

Graphene oxide (GO) nanosheets, which could be obtained by the oxidation and exfoliation of graphite, possess plentiful functional groups such as hydroxyl, epoxide and carboxyl ones. Such functional groups could be used for the crosslinking of various polymer matrices (Ha and Ellison, 2018). They could also be transformed into epoxide (Shen *et al.*, 2013), amino (Nonahal *et al.*, 2018), vinyl (Vesile *et al.*, 2019) and thiol groups (Luo *et al.*, 2016) for different polymer matrices.

As another candidate, GO could generate free radicals upon heating, enabling covalent crosslinking of styrene-butadiene rubber (SBR) (Xing *et al.*, 2017), allowing better mechanical properties than SBR crosslinked with conventional sulfur or dicumyl peroxide.

Other carbon nanomaterials

Well-crosslinked polybenzoxazine (PBz) networks were designed by the condensation of benzoxazine in presence of amine-functionalized carbon balls (CBs-NH₂) (Periyasamy *et al.*, 2020). The thermal and mechanical properties of the nanocomposites (PBz/CBs-NH₂) were found to be outstanding compared with those of the neat PBz.

POSS and Silica Nanoparticles

Polyhedral oligomeric silsesquioxane (POSS), cube-octameric framework with an inorganic core of about 0.5 nm, has attracted intense interests for the crosslinked nanocomposites, owing to the eight organic corner functional groups. Thiol-modified POSS (POSS-SH) has been used as crosslinker for poly(styrene-*b*-butadiene-*b*-styrene) (SBS) via the thiol-ene reaction (Bai *et al.*, 2014). With 1% POSS-SH, the maximum of stress at break of 23.4 MPa and elongation at break of about 1000% were achieved, distinctly different from the conventional inorganic filler reinforced elastomer where the increase of stress was usually sacrificed by the decrease of elongation. It has been explained that the SBS changed from the circle inland structures to lamella structures in the resultant elastomers.

Low density polyethylene (LDPE) has been crosslinked with the octavinyl polyhedral oligomeric silsesquioxane (OVPOSS) as crosslinker, in presence of dicumyl peroxide (DCP) as initiator for the radical reaction (Wu *et al.*, 2014). The storage modulus increased while the thickness of the lamellar crystal of polyethylene decreased because of the restricted chain mobility and folding to form crystal domain. The OVPOSS has also been used for the photo-crosslinking of poly(propylene fumarate), showing distinct physical properties and promoted MC3T3 cell functions (Wang *et al.*, 2011).

To improve the ablation resistance, hydroxyl-terminated polydimethylsiloxane was crosslinked with multi-ethoxy POSS at room temperature (Liu *et al.*, 2020a). Besides the strengthened mechanical strength, the thermal stability and heat shielding properties of composite were also enhanced, owing to the effective crosslinking with the uniformly dispersed POSS. The cross-linked hybrid composites have also designed with the multimethacryloxy- (Przadka *et al.*, 2015), methacrylate- or thiol- (Ito *et al.*, 2014), or octa(3-azidopropyl)- (Zhang *et al.*, 2020a) substituted POSS.

The hydrolysis-condensation approach seems a simple method to fabricate the crosslinked composites with in situ generated silica particles as crosslinker. However, because of the release of small molecules during the sol-gel process, it could only be used for the fabrication of hybrid thin films. For example, Polydimethyldiphenylsiloxanes/silica interconnected networks were designed by the reaction between the polydimethyldiphenylsiloxane- α,ω -diols and tetraethoxysilane (TEOS) (Cazacu *et al.*, 2010). With a high silica content, the enhanced thermal stability was achieved without crystallization because of the in the dense silica network.

Other Nanomaterials

γ -Methacryloxypropyltrimethoxysilane (MPTS) modified nanoclays (Liu *et al.*, 2014d; Zhu *et al.*, 2016a) and TiO₂ nanotubes (Villenas *et al.*, 2015) have been also used as multifunctional crosslinkers in the in-situ polymerization of vinyl-based monomers. The higher Vickers microhardness and better thermal stability were achieved owing to the gelation, although it might decrease the processability of the resultant nanocomposites.

Carbon nanotubes-silica (CNTs-SiO₂) nanohybrids have also been designed as multifunctional crosslinkers for the solution styrene butadiene rubber (*s*-SBR), via surface modification with MPTS (Wang *et al.*, 2013). The nanohybrids accelerated the vulcanization process and improved the crosslinking degree of vulcanizates. With 10 phr (parts per hundred of rubber), The tensile moduli at 100% elongation (M100) and tensile strength had 54% and 28% increase, respectively. Largely enhanced storage modulus and slightly increased thermal conductivity were also obtained for the resultant vulcanizates.

Compared with the crosslinking via the condensation reaction which could only be used for the fabrication of crosslinked aerogels, coatings or films, the crosslinking via the ring-opening reaction of epoxide and thiol-ene click reaction show promising potential, owing to the addition reaction characteristics.

Functional Materials

Adsorbents and Hydrogels for Biomedical Applications

Inorganic nanomaterials have been widely incorporated into the adsorbents and hydrogels to enhance the strength of polymer matrices. The inorganic nanomaterials, which were encapsulated or conjugated into the crosslinked polymeric networks, played an important role in the formation of the porous structure of the nanocomposite adsorbents and hydrogels, subsequently possessing obvious effect on the swelling and adsorption behaviors.

Chen, Xiong and Peng *et al* designed poly(N-isopropylacrylamide-co-dimethylaminoethyl methacrylate) hydrogels co-crosslinked with both organic crosslinker and inorganic crosslinker, N,N'-methylenebis(acrylamide) and OVPOSS, respectively (Chen *et al.*, 2013). Due to the microphase separation, the interconnected micropores were produced, endowing a faster deswelling rate.

The composite hydrogels could be synthesized by the crosslinking of the ready-made polymers with functional nanomaterials as crosslinkers. For examples, polymer hybrid hydrogels were synthesized by mixing a water-soluble polymer with trimethoxysilyl side groups with silica nanoparticles (Takafuji *et al.*, 2011). Besides, amphiphilic composite nanoparticles were designed by the reaction of

Fig. 3 Nanocomposite hydrogels with functionalized attapulgite nanorods as initiator and crosslinker respectively.

Fig. 4 Nanocomposite hydrogels with bi-functionalized attapulgite nanorods.

the urethane acrylate modified silica nanoparticles with amphiphilic reactive oligomers, in which the silica nanoparticles were chemically connected with each other through the hydrophobic crosslinked chains (Kim *et al.*, 2011). The obtained amphiphilic composite nanoparticles could be easily dispersed into water owing to their surface hydrophilic brushes. They showed high adsorption capacity toward hydrophobic molecules, and 100% of retention recovery and higher permeate flux in the ultrafiltration application.

The in-situ polymerization approach might be the promising method to fabricate nanocomposite hydrogels. Thermo-responsive hydrogels have been designed with enhanced mechanical properties, by the in-situ radical polymerization of N-isopropylacrylamide (NIPAM) and acrylamide (AAM) with vinyltriethoxysilane (VTES) modified GO as crosslinker (Wang *et al.*, 2017). The attapulgite-based initiator and crosslinker separately (Fig. 3) (Zhu *et al.*, 2014) or simultaneously (Fig. 4) (Zhu *et al.*, 2016b) have also been designed for crosslinked nanocomposite hydrogel via the in-situ radical polymerization.

Liu and co-workers designed attapulgite-based nanocomposite hydrogels with excellent reusability for selective adsorption of heavy metal ions via an “one-pot” inverse suspension polymerization, in which the attapulgite and the magnetic nanoparticles were surface-modified with polymerable groups as unique crosslinkers (Jiang and Liu, 2014a,b,c; Jiang *et al.*, 2015; Liu *et al.*, 2014a,b,c, 2015a). These nanocomposite hydrogel adsorbents showed outstanding anti-pressure resistance and the anti-shearing ability, without broken by loading a pressure of 3 kg as well as stirring for 2 h at 5000 rpm.

Hydroxyapatite nanorods and nanowires have been modified with acrylate groups to photo-crosslink methacrylated gelatin (GelMA) into gelatin cryogels (Cu *et al.*, 2020). The proposed composite cryogels showed promising potential as bone repairing materials, owing to excellent performances such as high porosity, appropriate water retention, shape recovery, and fast resilience features, as well as good biocompatibility and cell affinity.

Highly stretchable nanocomposite hydrogel has been fabricated via in-situ free radical polymerization of acrylamide with exfoliated two-dimensional MXene (Ti_3C_2) nanosheet as crosslinker (Zhang *et al.*, 2020b). The honeycomb-like fine structure with uniform pores were formed and attributed to the enhanced mechanical and drug release behaviors.

Shape Memory and Self-Healing Materials

Polyurethane (PU) has been widely used as the polymer matrix for the shape memory and self-healing composite materials. Electroactive shape memory polyurethane composite has been designed by in-situ crosslinking polymerization of HO-PCL-OH, 4,4'-methylene bis(phenylisocyanate) (MDI), and 1,4-butanediol (BD), in presence of hydroxyl modified MWCNTs (Jung *et al.*, 2010). The resultant composites possessed shape retention of 92% and shape recovery of 95%, respectively. Furthermore, the surface temperature and the shape recovery in applied electric voltage were strongly influenced by the dispersed structure of the MWCNTs in the obtained composites. Compared with the MWCNTs-based composites, the graphene-based one, which was also

synthesized with the similar method as above, showed higher modulus and breaking stress, and exceptional elongation-at-break. The resulting composite exhibited 97% shape recovery, 95% shape retention, enhanced shape recovery force, and fast electroactive shape recovery rate (Rana *et al.*, 2013).

Lee and Kim developed a novel method to fabricate the shape memory GO/PU composite, by UV curing the acrylate-terminated PU with allyl isocyanate modified GO (Lee and Kim, 2013). The glassy and rubbery state moduli, yield strength, T_g , shape fixity and shape recovery ratios were increased on adding up to 1.0 wt% loading. At higher concentrations, graphene is vulnerable to aggregation and auto-inhibition.

Biodegradable magnetic-sensitive shape memory Fe_3O_4 /poly(ϵ -caprolactone) (PCL) nanocomposites were designed via the photo-crosslinking of the vinyl-terminated PCL prepolymer with γ -(methacryloyloxy) propyl trimethoxy silane (KH570) modified Fe_3O_4 nanoparticles (Gao *et al.*, 2018). The nanocomposites possessed superior mechanical properties and excellent shape memory properties in both hot water and an alternating magnetic field.

The self-healing composite materials were mainly designed via the Diels–Alder (DA) reaction. Covalently bonded graphene oxide/polyurethane (GO/PU) composites with significant reinforcement and thermally healable properties were developed via in situ polymerization based on the DA reaction of bifunctional maleimide and the PU prepolymer, which was prepared with GO, MDI, and poly(tetramethylene glycol) and blocked by using furfuryl alcohol (FA) (Li *et al.*, 2014). With 0.1 wt% of GO, the tensile modulus of GO/PU composites increased from 9.80 MPa to 21.95 MPa, and the tensile strength and elongation at break of the GO/PU composites increased by more than 367% and 210% respectively, with a high healing efficiency of 78%. The similar self-healing GO/PU composite materials have also been designed with isocyanate modified reduced GO, and N-(2,3-dihydroxypropyl)-maleimide and furan-terminated hexamethylene diisocyanate trimer as chain extender and crosslinking reagent respectively (Du *et al.*, 2020), or maleimide modified GO and furan- and maleimide-contained linear PU polymers (Lin *et al.*, 2017).

Handique and Dolui designed a dual functionalized self-healing epoxy composite by forming the reversible crosslinked structure via the DA reaction between furfuryl grafted epoxy prepolymer, furfuryl modified MWCNTs and bifunctional maleimide (Handique and Dolui, 2019). The proposed epoxy composite possessed not only enhanced mechanical properties but also thermal remendability that enabled elimination of cracks, due to the successive retro-DA and DA reactions, which led to crack healing upto 79.82% healing efficiency in a controlled manner through chain reconnection.

The self-healing TiO_2 /polyimine composite has been fabricated by the reaction of the amino-functionalized TiO_2 microspheres with diethylenetriamine and terephthalaldehyde (Lv *et al.*, 2018). With optimized fillers amount of 3%, the tensile strength and modulus of the composite were enhanced by 14% and 97%, respectively, and tensile toughness is maintained at 4.3 ± 0.86 , which is the same with polyimine. Furthermore, the self-healing property was also achieved via the solvent-involved curing process.

Electrochemical Applications

Owing to the excellent dimensional and chemical stabilities of the novel crosslinked composite materials, they have been widely used as membrane in electrochemical fields, especially as the proton-exchange membranes for direct methanol fuel cells (DMFCs). For the special application, the sulfonated poly (arylene ether ketone) (SPAEC) has been mainly used as the polymer matrix, with the help of sol-gel technology. The hybrid proton-exchange membranes have been designed by the crosslinking of SPAEC with pendant propenyl moiety via radical process in presence of vinyl-functionalized silica (Feng *et al.*, 2010). With a silica content of 8%, the methanol permeability coefficient was $6.02 \times 10^{-7} \text{ cm}^2/\text{s}$, a 2.64-fold decrease compared with that of the pristine SPAES membrane. Chemically stable hybrid polymer electrolyte membranes have been designed by a combination of silane-crosslinking and thiol-ene click chemistry based on SPAEC as a proton exchange membrane for direct methanol fuel cell applications (Gao *et al.*, 2012). It was found that the Si-O-Si cross-linked structure makes a great contribution to the improvement of dimensional and oxidative stabilities. By using two functional silanes, 3-glycidoxypropyl-trimethoxysilane and 3-mercaptopropyl-trimethoxysilane in the silane-crosslinking, the proton conductivity of the hybrid membrane was 0.20 S/cm at 80°C (Lin *et al.*, 2011).

Sulfonated polyimide (SPI)- SiO_2 hybrid proton-exchange membranes have been designed by the co-hydrolysis and condensation of 3-glycidoxypropyltrimethoxysilane and TEOS in presence of amino-terminated SPI prepolymers (Liu *et al.*, 2010). The introduction of SiO_2 improved the methanol resistance while retaining good proton conductivity. With 30% of SiO_2 , the membrane possessed a proton conductivity of 10.57 mS/cm at 80°C and methanol permeability of $2.3 \times 10^{-6} \text{ cm}^2/\text{s}$ possibly because the crosslinking structure and SiO_2 phases formed in the hybrids could retain water and were helpful to proton transport.

Crosslinked poly(ethylene glycol) (PEG)/sulfonated polyhedral oligosilsesquioxane (sPOSS) hybrid membranes have been fabricated with poly(ethylene glycol) (PEG) and sulfonated polyhedral oligomeric silsesquioxane (POSS-SO₃H) with urethane crosslinks (Chang and Shin, 2011). The proton conductivity increased while the methanol permeability decreased with increasing POSS content in the hybrid membrane. The proposed hybrid membranes demonstrated proton conductivities comparable to that of Nafion 117 while exhibiting lower methanol permeability as compared to Nafion 117.

Crosslinked sulfonated poly(vinyl alcohol)/sulfonated MWCNTs nanocomposite membranes have been designed by facile crosslinking of sulfonated poly(vinyl alcohol) with sulfonated MWCNTs (Yun *et al.*, 2011). The composite membranes exhibited excellent proton conductivity ranging from 0.032 to 0.075 S/cm as well as low methanol permeability ranging from 1.12×10^{-8} to $3.32 \times 10^{-9} \text{ cm}^2/\text{s}$ at 60°C.

Graphene-based hybrid membrane has been fabricated by crosslinking the 4-chlorostyrene functionalized GO with sulfonated polysulfone (Yang *et al.*, 2018). It possessed a high proton conductivity of 0.462 S/cm at 90°C under hydrated conditions, with a low methanol permeability of $1.71 \times 10^{-6} \text{ cm}^2/\text{s}$ at 30°C.

Polybenzimidazole (PBI-OO) based composite membranes have been designed for the high temperature proton exchange membrane fuel cell (HT-PEMFC) application, by thermal curing of polybenzimidazole (PBI-OO) with the sulfophenylated TiO_2 particles (Krishnan *et al.*, 2018). It showed the highest uptake of 392% and a proton conductivity of 98 mS/cm at 160°C.

Miao *et al.* (2018) developed a mussel-inspired strategy to fabricate the rGO-based anion exchange membranes, by crosslinking the quaternized polysulfone (QPSU) with polydopamine-functionalized rGO. With 1.5% addition of the functionalized rGO, the membrane possessed 57% improvement in the hydroxide conductivity than that of pure QPSU membrane and reached the highest value of 61 mS/cm at 80°C. Furthermore, the crosslinked membranes exhibited strong dimensional stability, good mechanical strength, comparable alkaline stability and improved methanol permeability.

Novel gel polymer electrolyte has been designed for the rechargeable lithium batteries, by crosslinking the epoxycyclohexyl POSS with amine-terminated butadiene-acrylonitrile copolymer (Li *et al.*, 2012). It exhibited ionic conductivity of 2.0×10^{-4} S/cm at 30°C and good electrochemical stability to 4 V from cyclic voltammogram tests.

Functional Coatings

Waterborne polyurethane (WPU)/polyphenylsilsequioxanes (PPSQ) coating films were designed by the in-situ sol-gel reaction between phenyltrimethoxysilane and the alkoxy silane side-groups in WPU during film formation (Li *et al.*, 2018). The proposed method could efficiently avoid the phase separation in composite films prepared by physical blending, by forming more homogeneous crosslinking structures in the polymer matrix. Owing to hybrid networks with confined phase separation scales, the enhanced modulus, tensile strength and thermal stability were achieved with decreased water absorption.

Epoxy hybrid composites have been fabricated by curing brominated epoxy resin with octaaminophenyl POSS (Chen *et al.*, 2012). With 1% of octaaminophenyl POSS, the thermal and mechanical properties of the composites were enhanced while the water absorption declined significantly. Besides, the dielectric constant was 0.5 less than that of the epoxy resin in the range of 100 Hz–40 MHz.

Facing the conflict between dielectric constant and breakdown strength in the high-temperature ceramic/polymer nanocomposites for energy storage applications, a new strategy has been established to simultaneously improve breakdown strength and discharged energy density by a step-by-step, controllable dual crosslinking process, in which a strengthened interface was constructed between the heatresistant poly(arylene ether sulfone)s (DPAES) and BaTiO_3 nanoparticles with bisbenzocyclobutene groups to reduce molecular chains relaxation under elevated temperatures (Liu *et al.*, 2020b). The dual crosslinking procedures were controllable via tuning temperature and time of the chemical reaction: i) the polymer chains crosslinked to the surface-treated inorganic fillers at a lower temperature, which can strengthen the interfacial interaction at the organic–inorganic interface, inhibiting the formation of interfacial defects and limiting the local molecular changes motion in the same time; and ii) the rest polymeric matrix were crosslinked at a higher temperature which can further limit molecular chains motion in the majority part of the composite matrix. The proposed strategy is expected as a promising avenue for compact, flexible, and high thermal stable high energy capacitive energy storage devices at relatively high temperatures.

WPU-based anticorrosive coatings have been developed by curing the WPU molecules with polycarbodiimide modified GO (Cui *et al.*, 2020). The superior anticorrosive properties benefited from the barrier properties of well-dispersed graphene layers, the crosslinking structure along the functionalized graphene/WPU interfaces, as well as the improved water resistance of the coatings.

Thermally Conducting Polymer Materials

Thermally conductive MWCNTs/epoxy nanocomposites have been prepared by curing epoxy resin with different diamine-functionalized MWCNTs as both co-curing agents and conducting fillers (Choi *et al.*, 2017). With the same MWCNTs concentration, the crosslinking degree was affected by the diamines used. A high crosslinking density enhanced the thermal conductivity via phonon transport, but for high MWCNTs concentrations, a high crosslink density hindered the formation of a percolating network and lowered the thermal conductivity. The highest thermal conductivity of 0.283 W/mK was achieved with 3% of the octamethylenediamine modified MWCNTs.

The thermally conductive epoxy nanocomposites have also been designed with poly(glycidyl methacrylate)-grafted graphene as co-curing agent (Oh *et al.*, 2019). With a functional graphene content of 7%, the thermal conductivity reached 0.75 W/mK, meaning a thermal conductivity enhancement of 249%.

To balance the thermal conductivity and peel strength of the acrylic pressure-sensitive adhesive (PSA) with perspective for application in miniature electronic industries, bifunctional isocyanatoethylmethacrylate modified GO has been incorporated in the in-situ polymerization of acrylic monomers, followed with UV curing (Vu *et al.*, 2019). Within the range of filler content of – 3% and UV-radiation dosages of (400–3000) mJ/cm², the thermal conductivity and peel strength of the acrylic PSA-system under investigation varied in the range of 0.17–1.03 W/mK and 2831–299 g/25 mm.

Gas Barrier Membranes

Ha, Park, Ha, *et al.* developed a simple process for strong and flexible elastomer from a reactive mixture of GO and functional telechelic poly(dimethylsiloxane) (PDMS) (Ha *et al.*, 2016a). The resultant composite elastomers were highly crosslinked but highly flexible such that it can be stretched up to 300% of its original length. As a single gas barrier membrane, the gas permeability decreased 45% for N_2 , O_2 , CH_4 or CO_2 by incorporating 1% of GO, indicating its potential use in practical applications. Increasing the wt% amount of GO to 8%, the gas permeability decreased more than 99.9% (Ha *et al.*, 2016b).

Conclusion and Prospects

In summary, the reported works demonstrated that successful enhancement of the crosslinked polymer matrix composite materials with inorganic nanomaterials as crosslinking agents especially the mechanical and thermal properties, owing to the covalent crosslinking as well as the uniform dispersion of the inorganic nanomaterials. Furthermore, conductive carbon nanomaterials could also endow the electric and thermal conductivity, except the barrier function of layered graphene.

However, the release of small molecules in the condensation reaction is still a challenge in the crosslinking during molding approach, limiting its application for only crosslinked aerogels, coatings or thin films. The crosslinking via addition reaction should be a promising direction in the future research. Furthermore, the UV-irradiation crosslinking could only be used for the coatings or thin films, but not bulky materials. So the thermal-induced addition reaction might be the most practical technology to design and manufacture of the high-performance and low-cost polymer matrix composite materials for various applications, such as DA chemistry.

Introduction

The production of polymer matrix composites is a tedious method, which includes the strategy and development, fabrication, processing, analysis, and reduction of cost. The suitable fabrication processing methods with optimal choice of polymer matrices, reinforcements (fillers) such as inorganic, organic and hybrids, fiber length, fiber weight, percentage concentration, strategy, and other parameters to be taken in to attention. Polymer matrix used as either thermosetting or thermoplastic polymers, with suitable reactive additives. Reinforcing fillers with varying nature, continuous or discontinuous geometry, and random/oriented structure are to be deliberated. Fibrous reinforcements are categorized in to one dimensional (yarn and roving), two dimensional (woven, mat, and fabric wool), and three dimensional (fabric and braid) nature (Thomas *et al.*, 2012; Shalin, 1995; Njuguna, 2016; Wang *et al.*, 2011; Devaraju and Alagar, 2018; Ratna and Karger-Kocsis, 2008; Rajak *et al.*, 2019; Barbero, 2017; Hull and Clyne, 1996; Vijay Kumar *et al.*, 2019; Wang *et al.*, 2017; Hussain and Hojjati, 2006; Soutis, 2005; Saxena and Maiti, 2020; Advani and Hsiao, 2012).

Composite materials are used in different types of engineering applications where excellent performances are warranted under harsh and hostile working environmental conditions. Such conditions, the composite materials employed are required to possess the distinctive high performance, thermal, mechanical and tribological properties with a lesser weight and a higher resistance to degradation appropriate to warrant safety and cost-effectiveness (Thomas *et al.*, 2012; Shalin, 1995; Njuguna, 2016; Wang *et al.*, 2011; Devaraju and Alagar, 2018). Polymer matrices inherently have benefits over other materials including ceramics and metals. They are extensively utilized in variety of engineering applications due to their inimitable advantages including simple production method, lightweight and ductility. Polymer matrix composites are broadly utilized over a long period. They are mostly polymer composites typically reinforced with inorganic fillers. Since, they expected to possess the combined properties of both organic matrix and inorganic filler. Further, the inorganic reinforcement also exhibits the high thermal, mechanical stability and rigidity. Similarly, the polymer matrix contributes the ductility, flexibility, and easy processing capability of the composites.

Polymer matrix composite materials consist of two or more diverse materials that are either chemically/physically networked together. Each of the constituents retains their inimitable distinctive properties. Generally, polymer matrix composites comprise of two phases viz. matrix phase (organic polymer) and reinforcement (inorganic fillers). The matrix (organic polymer) segment is the continuous phase and the inorganic reinforcement filler are either discontinuous or continuous according to their nature. The inorganic filler reinforcement is responsible for load bearing and strength properties of the composites and the polymer matrix phase holds the filler reinforcements intact with integral part of the composites with firm adhesion. The polymer matrix composites are deliberated as vibrant materials in the field of advanced composites, owing to their collective properties, such as light weight, high stiffness, good toughness, efficient strength, good thermal properties, resistance to flame, fire, weather, moisture, fouling and corrosion, and better electrical behavior (Thoppul *et al.*, 2009; Sreenivasulu *et al.*, 2018; Mostafa *et al.*, 2017; Babu *et al.*, 2018; Chung, 2017; Benzait and Trabzon, 2018; Parikh and Gohil, 2015; Mahesh *et al.*, 2020; Kumar *et al.*, 2020; Benin *et al.*, 2020; Wanasinghe *et al.*, 2020; Gan *et al.*, 2020). They are extensively used in various high performance industrial, engineering and aerospace applications (Njuguna and Pielichowski, 2003; Mangalgiri, 1999; Quilter, 2001; Ghori *et al.*, 2018; Rana and Figueiro, 2016; Hamerton and Kratz, 2018).

Polymer matrix composites (PMCs) consists of a kind of continuous or short fibers that are embedded in polymer (organic) matrix. In the case of ceramic matrix composites (CMCs), the filler is used mainly to enhance the fracture toughness, the filler in a PMCs offers better strength and stiffness. The PMCs strength properties namely mechanical strength and load bearing behaviors are contributed by the filler (fiber) reinforcement. The purpose of the polymer matrix is to effectively bond the reinforcements together and to transfer stress/load between them. The processability of PMC materials mostly be influenced by the polymer matrix. The viscosity and the service life of the polymer matrix materials are directly influenced by the impregnation of the filler materials, fabrication of composites and prepregs storage. More prominently, the fabrication methods (molding) and processing parameters of composites are predominantly insistent by the polymer matrix resin. PMCs are used in nearly most of all sectors of modern life viz., from appliance constituents to vital components of automotive parts.

PMCs are most popular owing to their cost competitive and simple and amenable production methods. Certain of the short comings, that is, inferior behavior of the PMC are lower thermal resistance and higher coefficient of thermal expansion (CTE), which are compensated by the selection and use of appropriate additives and reinforcements.

There are two types of polymer matrix materials used conventionally for the fabrication general purpose and advanced composites: Thermosetting (phenolics, epoxies, benzoxazines and etc.) and thermoplastics (polyethylene (LDPE and HDPE), polypropylene, acrylics, nylon, and etc.) due to various reasons viz., availability, amenable processing and affordable cost. Similarly, the reinforcements preferably used for the PMC are glass fiber, carbon fiber and Kevlar fiber (aramid).

Properties of Polymer Matrices and Composites

PMCs properties might be expected by the rule of combinations. PMCs are used for production of primary and secondary aerospace structural components, boat assemblies, kayaks, canoes, automotive components, radio controlled transportation, sport components (skis, golf clubs, fishing rods, tennis racquets, and etc.), bullet-proof jackets and additional armor components, clutch and brake linings.

Properties of PMCs are influenced by the chosen fibers properties, alignment of fibrous reinforcement, and weight percentage of the fibers and nature of the matrix.

Types of Reinforcements and Their Uses

Use of neat polymers (without reinforcement) as structural materials is inadequate by inferior mechanical properties, for example, the tensile strength of epoxy is about 140 MPa (20,000 psi). Moreover to somewhat low strength, polymeric materials hold lower impact resistance. Hence, the filler reinforcement of polymers by robust fibrous network permits production of PMCs considered by the subsequent properties, viz., high stiffness, better tensile strength, improved fracture toughness, very good resistance against abrasion, puncture, and corrosion and cost competitive.

Application of Polymer Matrix Composite Materials

PMCs are widely used in modern life in the form of products ranged from device components to a massive collection of automotive components owing to their inexpensive and simple and amenable fabrication techniques. Major applications of PMCs including (Jose and Joseph, 2012; Wang *et al.*, 2011):

In automotive sectors – Fabrication of panel bodies, doors, drive shaft, leaf springs, bumpers, race vehicle bodies, and etc.

In aerospace sectors – Utilized in the fabrication of primary and secondary structural components for passenger airbus, space shuttles, military aircraft, and satellite systems. The major importance of using PMCs are to reduce the weight of aircraft, which reduces the fuel consumption and improve the performance of aircraft, and to lower its costs.

In marine sector – Used to fabricate the boat/marine body components using fiber glass PMCs, kayaks, and canoes.

In sports equipments – Used in footwear, fabrication of sports components and equipment and other goods due to their lower weight and higher strength performances.

In bio-medical sectors – Used in medical implants, devices fabrication for orthopedics, body parts for MRI scanners, tables for X-rays, and prosthetics.

In electrical sectors – Electrical panels, printed circuit board, switch-gear, electrical connectors and insulators. Also used in fabrication of electronic devices including Li-ion, capacitors, and bendable batteries and portable digital equipment covers including head-phones, etc.

Protective equipment – Since PMCs can judiciously survive excessive warm or icy and other harmful conditions, they are habitually used for the preparation of bullet-proof jackets and other armor products.

Industrial – PMCs are used in the fabrication of storage container for chemicals, high pressure containers, valves and pump housing. Also PMCs are used in blades, impellers, blower and motor covers and etc.

Structural – PMCs are used to restoration of bridges (flyovers) and other erection materials and equipments, including booms, blades for wind-mill, and cranes.

Role of Polymer Composite Materials in the 21st Century

The role and some of the uses of PMC at present are listed below:

- (1) Five-axis weaving expertise for the future generation of aircraft and mechanical enactment of multi-axis weave structures.
- (2) Non-crimp fiber implements for helicopters composite components.
- (3) Non-crimp braided carbon fiber filled PMCs for aeronautic applications.
- (4) Finite element modeling of textile filled composites and relationship with-real testing.
- (5) Textile composites in ballistics: modeling the material and failure response.
- (6) 3D textile composites: mechanical-progressive failure modeling and strength predictions.
- (7) Long-term resilience of plain weaves polymer composites.

Thermal Analyses of Polymer Matrices and Composites

Thermal analyses are the significant tool to characterize the polymer composites to predict and ascertain their high temperature applications. A complete assessment of the thermal behavior of a material would requires the following analyses including DSC, TGA/DTA, and DMA.

Fig. 1 TGA thermogram of epoxy hybrid composites (a) G-E, (b) Al_2O_3 + G-E, (c) Al_2O_3 + SiO_2 + ATH + G-E. Copyright 2016. Reproduced with permission from Suchitra, M., Renukappa, N.M., 2016. The thermal properties of glass fiber reinforced epoxy composites with and without fillers. *Macromolecular Symposia* 361, 117–122, WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim.

Morphological Analyses of Polymer Matrices and Composites

In order to precisely study the in-depth arrangement textural morphology and structure of the fabricated composite materials, the following analysis are performed: XRD, XPS, AFM, SEM, TEM.

Epoxy Matrix Composites

Epoxy resins are unique of the greatest predominantly used thermosetting resins for production of composite materials. Epoxy based PMCs are extensively used in variety of engineering applications including construction, aerospace, automotive, marine, oil and gas industries, owing to their cost competitive, lower weight, minimal shrinkage, good thermal and mechanical performances, superior electrical properties good strength and stiffness, long fatigue life, excellent adhesion behavior to wide range of substrates and good resistance to moisture, weather, solvent, fire and heat (Dusek, 1985; Ciesielski *et al.*, 2017; Toldy *et al.*, 2011; Vengatesan *et al.*, 2011; Devaraju *et al.*, 2013; Selvi *et al.*, 2019a; Ashok Kumar *et al.*, 2002; Alagar *et al.*, 1999; Bondzic *et al.*, 2006; Alagar *et al.*, 2000b; Nagendiran *et al.*, 2010; Alagar *et al.*, 2000a; Matykiewicz, 2020b; Sapiai *et al.*, 2020; Mittal *et al.*, 2016).

Suchitra research group reported the thermal and morphological behavior of glass fiber filled epoxy matrix composites using inorganic fillers (such as alumina, silica, and alumina trihydrate) (Suchitra and Renukappa, 2016). For the fabrication of epoxy composites they used pultrusion and ultrasonication techniques. They studied the thermal and morphological properties using DSC, TGA and SEM techniques. From DSC, the glass fiber reinforced composites possess improved values of T_g than the neat and other hybrid systems. TGA thermogram of the all the PMCs are depicted in Fig. 1. From the TGA, it is observed that GF reinforced epoxy composites exhibited good thermal stability (Initial degradation and maximum degradation) when compared to the neat epoxy system. This might be due to the presence of reinforcement in the epoxy matrix, which prevents the distribution of the volatile decomposition products.

The surface morphology and dispersion behavior of GF reinforced epoxy composites are checked with SEM and presented in Fig. 2. From SEM images, it was perceived that glass fibers are well dispersed in epoxy and arranged homogeneously. The reasonably distributed patterns were attained using the approach engaged for formulating the epoxy matrix composites.

Ghasem Naderi research group reported (Esmizadeh *et al.*, 2016) the synergistic properties of nanosized clay (NC) and carbon nanotube (CNT) filled hybrid epoxy composites and studied their thermal and morphological properties. Thermal performances of the hybrid epoxy composites were studied using TGA, HDT and DMA techniques. The thermal results obtained indicated that the developed hybrid epoxy composites showed relatively higher degradation temperature, HDT and T_g compared to those of neat system. The value of T_g increased to 123°C for 0.2% CNC introduced epoxy composites from 113°C for neat epoxy system. From TGA analysis (Fig. 3) the developed epoxy composites showed higher thermal degradation (initial degradation and maximum degradation) and char yield compared to the neat epoxy matrix. The initial degradation increased from 340°C to 344°C, T_{max} from 369°C to 375°C and residual char increased to 13% from 10% respectively. From HDT analysis, the 0.2% CNC-epoxy composites show higher values of HDT (increased by 9.7°C compared to that of pristine epoxy) than other systems. In summary, thermal performances of epoxy with 0.2% CNC and epoxy with 0.2% PNC, among them CNT the enhanced the higher values of T_g , T_d , residual char, and HDT of epoxy than those of NC. This may be due to the good compatible and dispersion nature of CNC in to epoxy when compared to those of PNC (poor dispersion). This result supports that CNT and NC have a more substantial synergistic influences in enhancing the thermal performances of the resulting CNC epoxy composites.

In order to understand the interaction between epoxy matrix and nano-fillers, SEM was performed to ascertain the surface and fractured morphology of epoxy hybrid composites and the images obtained are presented in Fig. 4. Fig. 4 shows the fractured

Fig. 2 SEM image of epoxy hybrid composites (a) G-E, (b) Al_2O_3 + G-E, (c) Al_2O_3 + SiO_2 + ATH + G-E. Copyright 2016. Reproduced with permission from Suchitra, M., Renukappa, N.M., 2016. The thermal properties of glass fiber reinforced epoxy composites with and without fillers. *Macromolecular Symposia* 361, 117–122, WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim.

Fig. 3 TGA thermogram of epoxy composites with different nanofillers. Copyright 2015, Reproduced with permission from Esmizadeh, E., Naderi, G., Yousefi, A.A., Milone, C., 2016. Thermal and morphological study of epoxy matrix with chemical and physical hybrid of nanoclay/carbon nanotube. *JOM* 68, 362–373. Springer, The Minerals, Metals & Materials Society.

surface of the various types of filler reinforced epoxy composites. From Fig. 4(a), the fractured surface of the neat epoxy was very smooth surface while filler introduced epoxy there was a substantial increase in roughness behavior of surface. The higher surface roughness was observed for 0.2% CNC filled epoxy system when compared to that of 0.2% PNC filled epoxy system due to the efficient interaction occurred between the CNC filler and epoxy matrix. This statement is in good agreement with the values of T_g obtained from the DMA characterization.

Yasmin *et al.*, developed the various weight loaded graphite platelets reinforced epoxy composites using anhydride as curing agent and studied their structural, thermal and mechanical properties (Yasmin and Daniel, 2004). The storage modulus and T_g of the epoxy composites showed increase with increasing weight content of graphite platelet, though, the CTE values decreased. The thermal stability of the composites indicated higher thermal stability and higher char residue than that of neat epoxy matrix. From

Fig. 4 Fracture surface morphology of (a) epoxy, (b) epoxy-NC, (c) epoxy-CNT, (d) epoxy-PNC and (e) epoxy-CNC by SEM. Dispersion status of NC (b') epoxy-NC, (d') epoxy-PNC and (e') epoxy-CNC with detection Si by EDX. Dispersion status of CNT: (c') epoxy-CNT, (d'') epoxy-PNC and (e'') epoxy-CNC by high-magnification SEM. Copyright 2015, Reproduced with permission from Esmizadeh, E., Naderi, G., Yousefi, A.A., Milone, C., 2016. Thermal and morphological study of epoxy matrix with chemical and physical hybrid of nanoclay/carbon nanotube. JOM 68, 362–373. Springer, The Minerals, Metals & Materials Society.

the TGA (Table 1), for neat epoxy, the T_i temperature is 360°C, while for the composites it increases to 366°C and 368°C for 2.5 wt% and 5.0 wt% platelet graphite filled epoxy systems respectively. Also, the epoxy composites show higher char residue at 800°C as the filler ratio increases. Where neat epoxy system displays a char residue of 10%, in case of composites exhibited 13% and 15% for 2.5 and 5 wt% graphite filled epoxy systems, respectively. Consequently, the introduction of platelet graphite filler in to epoxy resulted in prominent enhancement in thermal properties. This may be ascribed to the uniform dispersion of graphite filler in the composites that delays the dissemination of the volatile degradation products. The homogeneous dispersion of graphite platelet in epoxy system was checked with SEM technique. Fig. 5, displays the fractured surface of the neat epoxy matrix and 5% filler reinforced epoxy composites. For neat epoxy matrix, the crack typically pledges from surface flaws or higher stress areas. The mirror resembling area signifies the slow progress of crack-like deficiencies for neat epoxy matrix. The streaks next to the mirror resemble area are shear edges established by nucleation and transmission of micro shear regions within the epoxy matrix. While the 5% graphite filled epoxy composites displays the shear edges but only at the commencement when the crack progress rate is lower. Furthermore, the shear edges seem to be smaller and shorter compared to that of neat epoxy matrix. This might be owing to the graphite filler constrain the free rotation of polymer chains by crack tip pinning.

Mahato research group studied the thermal, mechanical, and morphological properties of Al_2O_3 nanoparticle embedded glass fiber reinforced epoxy composites (Mahato *et al.*, 2019). Thermal and morphological properties studied with DSC, DMTA and SEM analysis. From DSC and DMTA analysis, the values of T_g decreased with introduction of Al_2O_3 nanoparticles in to glass fiber reinforced epoxy (GE) composites. For 0.1 wt% Al_2O_3 -GE composites, the value of T_g decreased to 10.6°C when compared to that of neat GE matrix. Up-to 0.3 wt% Al_2O_3 -GE composites showed lower values of T_g after the increasing to 0.5% Al_2O_3 -GE composites, the value of T_g was increased. Fig. 6 show the surface morphology and dispersion ability of Al_2O_3 nanoparticles in GE. Among the composites, 0.1 wt% Al_2O_3 nanoparticles incorporated in to GE is homogeneously dispersed throughout the GE. While 0.5 wt% nano- Al_2O_3 /GE composites, the Al_2O_3 nanoparticles are showed a lot of agglomeration/aggregation in the GE composites. Generally, the higher concentration of Al_2O_3 nano-particles in to the epoxy matrix system lead to the agglomeration that diminishes nano- Al_2O_3 /epoxy interfacial interaction and ultimately results in lower strength.

Matykiewicz studied the effect of the bio-char additives (0, 2.5, 5, and 10 wt%) on the performances of carbon fiber filled bio-epoxy matrix composites (Matykiewicz, 2020a). Thermal stability composites studied with TGA in both air and inert atmosphere and the results are presented in Figs. 7 and 8 respectively. From TGA, the epoxy composites analyzed in a N_2 atmosphere, the introduction of bio-char considerably didn't affect their thermal performance. The $T_{10\%}$ degradation ascribed as on average of 330°C and the char residue at 800°C was in the range of 43%–45% (Table 1). In-case of air atmosphere; the thermal stability was increased with the increase in weight content of bio-char of epoxy matrix. The 10% weight loss was increased from 302 to 325°C, and the maximum degradation increased from 345 to 353°C.

The surface morphology of bio-char and bio-char-modified epoxy composites are studied with SEM technique and the images obtained are depicted in Fig. 9. From the SEM, bio-char was observed the size with an average diameter of 4–8 μm . In case of the bio-char filled epoxy composites observed that there is no bio-char aggregation/agglomeration, which specifies good association between bio-char and epoxy matrix (Fig. 9).

Karvanis research group developed basalt fiber reinforced epoxy matrix composites (BFRP) and studied their thermal and mechanical properties (Karvanis *et al.*, 2020). From the TGA, it is indicated that there is a sharp deterioration started at 260–300°C during the decomposition of the BFRP matrix composites both in air and inert environment and this may be due to the epoxy matrix weight loss. Compared the thermal degradation of BFRP matrix composites in air and nitrogen atmosphere, it can be observed that the basalt fibers are not affected much up to 900°C while in air atmosphere the epoxy matrix has completely vanished before the temperature of 550°C. From DTG spectra, it was observed that the maximum degradation peaks which relate to the maximum decomposition of composites. For BFRP matrix composites, in N_2 atmosphere, the peak (T_{max}) is noticed at 341°C, which is represents to the epoxy matrix degradation, while in air atmosphere, two decomposition peaks are observed at 336.4 and 458.6°C.

Kavimani research group reported the synergistic enhancement of GO and TiO_2 particles reinforced in to epoxy matrix composites through compression molding fabrication technique (Kavimani *et al.*, 2020). Thermal properties of 1.5 wt% GO reinforced composites is studied using TGA. Here, three stages of degradation were observed for GO reinforced epoxy composites. The first stage degradation arises from 30°C to 370°C with the weight loss of 23.3%. Second stage degradation started at 373°C with the weight loss of 63.3% and the final stage of degradation occurred at 470°C with the mass loss of 91.4%. Thermal degradation of composites with respect to residual char is presented in Table 1. The fractured surface morphologies of the developed epoxy matrix and epoxy composites are displayed in Fig. 10. From the SEM images, the neat epoxy (Fig. 10(a)) displays the very smooth surfaces with brittle fracture. In case of composites, the micro voids observed may be owing to de-bonding impact of filler from epoxy matrix. Rough surface fractured morphology with plenty of edges infers the existence of ductile fractured mechanism.

Dubois group reported the varying weight percentage concentration (0.1, 0.3, and 0.5 wt%) of aluminum hypophosphite ($AlPO_2$) nanofillers reinforced epoxy composites and studied their cure kinetics and thermal stability in order to utilize them for special high performance applications (Tikhani *et al.*, 2020). Cure behavior of various weight percentage concentration of AHP nanoparticles (0.1, 0.3, and 0.5 wt%) reinforced epoxy/amine system was studied using DSC with the heating rates of 5, 10, 15 and 20°C. From the Table 1, it is observed that the AHP incorporation in to epoxy matrix has subsidized to cure behavior of epoxy resin and the cure index (CI) values obtained indicates excellent cure states. Low concentration of AHP expedites the better dispersion in the epoxy matrix and inhibits physical restrictions including viscosity or dilution effect. At lower weight concentration (i.e., 0.1 wt%),

Table 1 Thermal properties of various filler reinforced epoxy matrix composites

the abated amount of aggregation, and at higher weight percentages (0.3 and 0.5 wt%), several dynamic sites presented in to the system are the reasons for excellent cure states. The value of T_g of cured AHP/epoxy composites was checked between 15°C and 250°C and the results obtained were compared with neat epoxy matrix (Table 1). The value of T_g is increased to 79.5°C from 73.2°C (neat epoxy matrix) for 0.1 wt% AHP/epoxy system, in the case of 0.5 wt% AHP/epoxy system the value of T_g was decreased to 69.5°C and this may explained due to the accumulation of AHP in the epoxy which could facilitates the molecular movement. For 0.3 wt% AHP/epoxy system also exhibits the similar T_g value (73.1°C) to that of epoxy system. The thermal properties of epoxy matrix and AHP/epoxy composites was checked using TGA and the values are presented in Table 1. The initial degradation temperature is lower for AHP/epoxy composites than that of the neat epoxy matrix and this may be due to the O=P–O bond (higher activity) when compared to that of C–O and C–C bonds in present in epoxy matrix, which is enhanced by higher concentration of AHP filler content and this contributes to lower initial degradation temperature. In case of char residue the 0.5 wt% AHP/epoxy composites shows the higher char residue (10.7%) when compared to that of other systems.

Jawaid research group developed the date palm fiber (DPF) reinforced epoxy composites (Alothman *et al.*, 2020) with fillers derived from palm tree portions including leaf sheath, leaf stalk, tree trunk, and fruit bunch stalk. Fig. 11 displays the TGA thermograms of the neat epoxy matrix and DPF composites. It was noticed that the DPF fibers reinforced with epoxy with different portions of the palm tree exhibit together the initial thermal degradation and maximum thermal degradation temperature were significantly lower than that of the neat epoxy matrix system. This might be owing to the decomposition of DPF fiber components including lignin, hemicellulose, and cellulose. Nevertheless, 2–3 times higher char residue values for the DPF/epoxy composites than that of the neat epoxy matrix. Among all, fibers acquired with tree trunk (L) was observed as better thermal stability (char residue of 22%) than compared to that of other systems. The values of T_g are observed between 60 and 65 °C for the neat epoxy matrix and composites and the results are presented in Table 1. Here, T_g values were found to be slightly lower due to the

reinforcement of DPF fiber into the epoxy matrix. Further, CLTE of the composites beyond the T_g is reliant on the enlargement of free volume, which relates to the dimension changes in the materials under load. Enlargement of the free volume over the T_g consequences in the lower in density, enhanced chain flexibility and more number of conformational changes in the polymer chains. Consequently, the thermal enlargement is larger in the epoxy system resulted in CLTE values are increased. In contrast, filler reinforced composites systems possessed the lower values of CLTE ([Table 1](#)).

Chiang *et al.* reported the development of functionalized carbon nanotubes (CNTs) reinforced epoxy composites and studied their thermal and flame resistant properties ([Kuan *et al.*, 2010](#)). CNT is functionalized with triethoxyvinylsilane (VTES). TGA and DSC characterization techniques are utilized to check the thermal performance of epoxy composites. The value of T_g increased to 160°C from 118°C and residual char of 9 wt% CNT epoxy composites was improved by 46.94% at 750°C. The integral procedural decomposition temperature (IPDT) was increased to 1571°C from 890°C. The LOI of epoxy composites was enhanced to 27 from 22 and the UL-94 altered to V-0 from V-1 when the CNT concentration increased over the 3 wt%. The developed epoxy composites can encounter to the desires of phosphorus-free and halogen-free environmental friendly flame-retardant materials for various applications.

Alagar research group reported the varying weight content (0.5, 1.0 and 1.5 wt%) of glycidyl functionalized mullite (GM) fiber reinforced epoxy composites and studied their thermal and mechanical properties ([Kanimozhi *et al.*, 2013](#)). The mullite fiber was prepared through sol–gel techniques and its surface was functionalized with 3-glycidoxypropyltrimethoxysilane. The data acquired from the various techniques revealed that the GM fiber filled epoxy nano-composites superior properties than the neat epoxy matrix. The 20 wt% weight degradation temperature of neat epoxy matrix, 0.5, 1.0 and 1.5 wt% GM reinforced DGEBA epoxy composites arises at the weight loss temperatures of 372, 329, 337 and 353°C, respectively ([Fig. 12](#)). The values of char yield obtained for the neat epoxy and GM fiber filled epoxycomposites are 0, 3.9, 8.9 and 12.1 at 700°C respectively.

The surface morphology of the neat epoxy matrix and the mullite fiber filled epoxy composites was studied by SEM and are presented in [Fig. 13](#). From SEM analysis, the neat epoxy system shows the smooth and fractured glassy surface indicated the brittle behavior. The SEM images of fiber reinforced epoxy composites clearly evidences mullite fibers are homogeneously dispersed throughout epoxy matrix with no cavity and no phase separation.

The same research group reported the NH_2 -POSS reinforced epoxy composites using structurally modified diamines used as curative ([Sethuraman *et al.*, 2014](#)). Data acquired from thermal, mechanical, electrical and surface properties were compared with the neat epoxy matrix. [Fig. 14](#) and [Table 1](#) shows the thermal decomposition properties of DDM, OMA, CPA and BPA cured epoxy

Fig. 16 TGA thermogram of neat CE/EP and OAPS/OG-POSS reinforced CE/EP nanocomposites. Copyright 2012, Reproduced with permission from Chandramohan, A., Dinkaran, K., Ashok Kumar, A., Alagar, M., 2012. Synthesis and characterization of epoxy modified cyanate ester POSS nanocomposites. High Performance Polymers 24, 405–417, from SAGE Publications.

matrices and POSS filled epoxy composites. From the results, it can be observed that epoxy matrices cured with all prepared diamine curatives have zero (0%) percent residual char at 700°C. While POSS filled epoxy systems increased the residual char agreeing to the percentage weight content of POSS loading, the 5 wt% POSS filled CPA amine cured epoxy system showed highest thermal stability with the char residue value of 25% at 700°C. TEM micrograph (Fig. 15) explains the homogeneous dispersion of POSS cages in the epoxy matrix with uniformity and it subsidizes to the better thermal and mechanical performances of the resulting composites.

Alagar research group reported the octa-functional polyhedral oligomeric silsesquioxanes [octaamino (OAPS) and octaglycidyl (OG)] reinforced epoxy modified cyanate ester nanocomposites prepared and studied the thermal and mechanical properties. From the values of T_g (Table 1) of neat CE/EP system is 234°C, while the introduction of OAPS and OG-POSS into CE/EP systems, the values of T_g increased up to 5 wt% (T_g – 251°C) and further addition of OAPS and OG-POSS decreased the T_g values of the composites. The TGA of neat CE/EP and POSS filled CE/EP composites are presented in Table 1 and Fig. 16 from the temperature range of 30–800°C. For the POSS composites system showed the $T_5\%$ weight loss decomposition temperature decreased (from 420°C to 379°C), while the residual char yield (increased to 33.6% from 19.7%) increased with an increasing the weight percentages of POSS. This might be owing to the inert silica layer in the POSS which act as protecting layer to prevent the further degradation of polymer matrix.

Surface morphology of CE/EP and POSS filled CE/EP systems are studied with XRD, SEM and TEM analysis. From XRD, the POSS reinforced system showed uniform dispersion with amorphous in nature. The fractured surfaces morphology of the neat CE/EP matrix and POSS composites systems obtained from SEM analysis are presented in Fig. 17. The morphology of the neat

CE/EP matrix shows smooth morphology and without any micro phase separation. For POSS filled composites shows the presence of a lot of “filari” shape looks like bamboo when they were pulled out. In addition the POSS cages were homogeneously dispersed in the CE/EP matrix. Further this was checked with TEM and the TEM images of the POSS filled CE/EP composites are depicted in Fig. 18. It is also observed from TEM analysis that POSS cages are dispersed homogeneously throughout the CE/EP matrix.

Benzoxazine Matrix Composites

Polybenzoxazines (PBZs) have received much great interest and consideration owing to their numerous beneficial properties connected with traditional phenolics, including outstanding chemical and heat resistance, flame and fire retardant, low K

Fig. 19 TGA thermograms of aramid pulp/carbon fiber filled PBZ composites at various aramid pulp: carbon fiber mass ratios (A) of 100:0 (●), 75:25 (▲), 50:50 (■), 25:75 (◆), and 0:100. High performance aramid pulp/carbon fiber-reinforced polybenzoxazine composites as friction materials. Composites Part B: Engineering 177 (1–10), 107280, from Elsevier.

dielectric, better mechanical stability, and reasonably low cost. Also they retain additional anticipated properties including minimal or no shrinkage during curing, low absorption of moisture, better dimensional stability, brilliant fire, smoke, toxicity (FST) properties, and vast molecular flexibility in the design (Kiskan, 2018; Ghosh *et al.*, 2007; Ishida and Froimowicz, 2017; Ishida and Agag, 2017; Santhosh Kumar and Reghunadhan Nair, 2010; Devaraju *et al.*, 2019b; Lyu and Ishida, 2019; Iuliana *et al.*, 2019; Sarawut *et al.*, 2013; Ramdani, 2017; Selvi *et al.*, 2019b; Devaraju *et al.*, 2019a; Krishnadevi *et al.*, 2019; Jamrozik *et al.*, 2020). These possessions offer extraordinary potential to alternative to epoxy, bismaleimide, phenolics, and etc., in number of industrial applications. For example, conventional benzoxazines are worthy aspirants for fabrication of prepregs used for aerospace structure, and are presently applied regularly in the aerospace sectors. It is assessed that over the 30% weight reduction may be achieved with the used benzoxazine composites to replacing the metal, which consequences in reduction in the fuel consumption, and emissions.

Fig. 21 TGA thermograms of fibers, neat PBZ and fiber reinforced PBZ composites. Copyright 2017, Reproduced with permission from Dayo, A.Q., Gao, B.-C., Wang, J., *et al.*, 2017. Natural hemp fiber reinforced polybenzoxazine composites: Curing behavior, mechanical and thermal properties. *Composites Science and Technology* 144, 114–124, from Elsevier.

Rimdusit group reported the development of aramid pulp/carbon fiber filled PBZ composites (Lertwassana *et al.*, 2019). They studied the possessions of carbon fibers and aramid pulps on thermal and mechanical properties, and tribological properties of composites are examined. The composites reveal higher thermal degradation and T_g temperatures, high friction coefficient, and better wear resistant. The developed PBZ composites might be useful as non-asbestos organic friction materials. From TGA (Fig. 19), the initial degradation T_{d5} % of PBZ composites raised with increasing the content of carbon fiber. Aramid pulp/carbon fiber filled PBZ composites with mass ratio of 100:0 (aramid pulp: carbon fiber) indicated the lower most T_{d5} % of 408°C increase of mass ratio of 0:100 exhibited the highest value of 437°C. It was noticed that the yield also improved with increase of the concentration of carbon fiber of the PBZ composites. The residual char values were in the range between 72.1% and 81.7% at 1000°C. Carbon fibers exhibited the high decomposition temperature with insignificant weight loss up to 1000°C (Fig. 19). The values of T_g of the PBZ composites were observed as 240, 244, 247, 262, and 265°C for mass ratios of aramid pulp:carbon fiber 100:0, 75:25, 50:50, 25:75, and 0:100, respectively. T_g values are elevated with increase in weight content of CFs. CFs might significantly constrain the movement of PBZ networks owing to the rigidity of CFs. These thermal results advised that CFs could enhance thermal stability of the PBZ composites.

Fig. 20 illustrates the worn-out surfaces of various weight ratio of carbon fiber: aramid pulp reinforced PBZ composites. Flaws and minor grooves were perceived on the surface of worn-out (Fig. 20(A)), inferring abrasive mechanism. In addition, small cracks were also perceived on PBZ composites surfaces after the introduction of CFs. Cracks and small grooves were decreased when CFs ratio increased in PBZ composites, prominent to improved wear resistance. Wear debris of PBZ composites were also studied to assess the tribological behavior by SEM and the results obtained are presented in Fig. 20. From SEM analysis, it was mostly observed plate shaped wear debris for all CFs reinforced PBZ composites. Certain spherical wear debris were also perceived only with aramid pulps reinforced PBZ composites. Carbon fiber/aramid pulp introduced PBZ composites might be possibly realistic as better performing friction materials.

Wang *et al.* reported the 5% NaOH (THF) activated hemp fibers reinforced bisphenol A-aniline based PBZ (PBA-a) by resin-fiber-resin composites (Dayo *et al.*, 2017). The effects of change in volume of fiber on the curing, thermal, thermo-mechanical and morphological properties of the PBZ composites were studied by DSC, DMA, TGA, and SEM. The results indicated that the NaOH treated hemp fiber reduce the curing temperature of benzoxazine, and increase the adhesion between matrix and fiber. From DSC curing, all hemp fiber reinforced BA-a blends showed lower initial exothermic peaks (T_i) and onset temperatures (T_p) when compared to that of neat BA-a monomer matrix. The T_i and T_p values were decreased to 177 and 230°C (hemp fiber from 0 to 25 vol%) from 213 and 246°C (neat BA-a), respectively. This reduction in the cure temperatures is due to the presence of -OH functional group on the hemp fiber, which act as catalyst to start the ring-opening polymerization at lower temperature. Further, it was also observed that the values of decomposition temperatures T_5 % (318–307°C) and T_{10} % (345–338°C) and residual char yields (28.5 to 28.0) of all hemp fiber reinforced PBZ composites (Fig. 21 and Table 2) were insignificantly affected with introduction of hemp fiber.

The SEM technique was used to assess the surface and fracture morphology of treated and untreated hemp fiber, and compatibility of fiber with PBA-a. From SEM (Fig. 22), better adhesion was perceived between fiber and matrix as increases of fiber fraction. Minor cavities were noticed on the fractured surfaces apparently owing to the deprivation of cellulosic and hemicelluloses

Table 2 Thermal properties of various filler reinforced polybenzoxazine matrix composites

components in the fiber surface during curing. The fracture surfaces exhibited the discreet gaps between matrix resin and fiber. Pull-out the fibers from the polymer matrix was found lower loading, causing the failure to test. However the fibers pull-out cavities also were diminished by increasing the weight content of fiber. These images afford exceptional explanation for the composites to support the data of mechanical properties.

The same research group reported the effect of alkali, cyclohexane/ethanol, and silane treatment of hemp fibers and their corresponding PBZ composites and studied the thermal, mechanical and morphological properties (Dayo *et al.*, 2018). From the studies lignin and hemicellulose in the fibers was removed after treated with cyclohexane/ethanol and alkali. The silane treatment enhanced the thermal properties of composites. The thermal stability of the composites was analyzed using TGA and are presented in Table 2 and Fig. 23. From the TGA thermogram, the $T_5\%$, $T_{10}\%$, decomposition temperatures and residual char was observed as 338°C, 365°C and 28.7%, respectively for neat poly(BA-a) matrix. In case of silane treated PBZ composites showed slightly lower $T_5\%$, $T_{10}\%$, decomposition temperatures and residual char values of 324°C, 346°C and 28.5% respectively. The thermal stability behavior of composite systems is lower than that of PBZ matrix. It was also noticed from thermal stability results that the thermal decomposition of the fiber reinforced PBZ composites can be reduced by the silane usage up to certain extent.

Fig. 22 SEM micrographs of the native hemp fiber, treated hemp fiber, fractured surface of PBA-a/THF. Copyright 2017, Reproduced with permission from Dayo, A.Q., Gao, B.-C., Wang, J., *et al.*, 2017. Natural hemp fiber reinforced polybenzoxazine composites: Curing behavior, mechanical and thermal properties. Composites Science and Technology 144, 114–124, from Elsevier.

The surface morphology of PBZ composites was studied with SEM and the results obtained are presented in Fig. 24. From the Fig. 24, neat PBZ perceived smooth surface endorses the brittle behavior of the PBZ. The fiber reinforced PBA-a/WHF composites showed numbers of cavities and fiber ruptures. These cavities are built-up on the fiber slip during rupturing, designating the smooth and glassy fiber surface. Further, the similar surface morphology was also observed for PBA-a/AHF composites. Further, the PBA-a/SHF composites, pull out fiber was completely roofed with the PBZ resin; this inferred that the treated silane fiber composites had efficient fiber and matrix interaction than the treated other composites. These outcomes are in good agreement with the formerly discussed efficacy coefficient for the SHF fiber PBZ composites.

Lomonaco research group developed the PBZ based bio-composites using natural fabrics of *Manicaria sacifera* (MS) (palm tree) and two BZ matrices prepared from bisphenol-A (BA-a) and phenol (*p*-a) (Oliveira *et al.*, 2020). They developed the bio-composites as bi-directional base treated fabrics reinforced with BZ resins (prepregs) and then polymerized in hot-press technique. The better compatibility of the BZ matrix with fabric was checked by SEM, which infers that base treated fabric attaining enhanced interfacial interaction. Thermal characterization results indicate the bio-based materials revealed excellent flame resistant properties. The $T_5\%$, $T_{10}\%$ decomposition temperatures and residual char values were slightly decreased for PBZ composites when compared to those of neat PBZ (Table 2 and Fig. 25). This slight reduction may be due to inherent nature of bio-fiber than the highly stable PBZ matrix. Though, the LOI values of bio-composites showed 29.1 and 31.1 of [BC(MS/BA-a)] and [BC(MS/P-a)], respectively, proved that the developed bio-composites from renewable feed-stocks qualifies for competent flame retardancy materials.

SEM technique was performed to check the surface fractured morphology of [BC(MS/BA-a)] and [BC(MS/P-a)] and are presented in Fig. 26. From SEM images, it was perceived that the fractured surface of BC(MS/P-a) indicates in a more organized

manner while, BC(MS/BA-a) shows the more uneven fiber pull-out from the matrix surface. Further, it was also observed that there was no phase separation (aggregation) between the matrix and fiber, indicating the firm and efficient adhesion in the interface region.

Wang research group reported the different weight concentration of silane treated natural hemp fiber (TNHP) filled cyanate ester/benzoxazine composites and studied their thermal and mechanical performance (Zegaoui *et al.*, 2018). Thermal properties of composites were studied with TGA and DSC analysis. From DSC results, it was noticed that the TNHP fiber reinforced CE/BOZ composites showed higher T_g values than those of neat CE/BOZ matrix. The values of T_g are improved with increasing the weight content of TNHP in the CE/BOZ composites. The T_g value was increased to 268°C (for 20% TNHP filled CE/BOZ composites) from 243°C for neat CE/BOZ. From TGA (Fig. 27), it was observed that the thermal performance was somewhat increased by introducing more and more TNHFs reinforcement in the CE/PBZ. The $T_5\%$, $T_{10\%}$ and residual char values were progressively improved from 341°C, 357°C and 27.1% for the CE/BOZ/TNHF-5 to 350°C, 367°C and 27.2% respectively for the maximum loaded TNHF in the CE/BOZ/TNHF-20. Such a regular increase in the thermal stability may be owing to the increasing high heat resistant behavior of TNHFs in the composites, which could reasonably increase the thermal properties of the composites by preventing the emission of volatile decomposition products, fragments and residual char formation.

In order to assess the interfacial adhesion between the CE/BOZ matrix and fiber, SEM images were accomplished to perceive the surface fractured morphology of neat CE/BOZ and its related composites and the results obtained are presented in Fig. 28. For neat CE/BOZ matrix, it was observed that smooth and glassy surfaces as well as regular river lines due to the high brittle behavior. In contrast, the composites showed small cavities and bubbles on the ruptured surfaces, which may be due to the concurrent degradation of hemicellulose and cellulose present in the fiber. It was also observed that the good bonding sites were developed between the fibers and CE/BOZ matrix as the fiber content increased. These SEM images also ascertain the outstanding mechanical performance achieved upon reinforcing varying amounts of TNHFs within the CE/BOZ matrix. Thus, the good thermal and mechanical performances observed for CE/BOZ blend composites suggested a potential application in the arena of construction, furniture, shipping and household products.

Koschek *et al.* reported the basalt fiber, glass fiber and carbon fiber filled PBZ composites using bisphenol-F/aniline based benzoxazine monomer (Wolter *et al.*, 2020). The FRPs displayed a uniform morphology with fully impregnated fibers and almost no porosity. CFs reinforced PBZ composites possess higher mechanical properties. Though, concerning the FST properties, glass and basalt reinforced PBZ outperformed CFs reinforced PBZ. To assess the impact of the different types of fiber filled PBZ composites on the thermal and thermo-oxidative stability was checked with TGA under nitrogen and ambient atmospheres condition and the results obtained are presented in Fig. 29 and Table 2. From TGA results, it was inferred that the inclusion of fiber reinforcement in to PBZ, the 2% and 10% mass loss degradation temperatures and residual char are increased. Mainly, the existence of fiber introduction reduced the quantity of polymer matrix that can decompose during thermal treatment. Moreover, GFRP and BFRP provide higher residual char than that of CFRP. For BFRP and GFRP char residue restored up-to 70%–71%, however CFRP char yield reduced 27 wt%. Mineral fiber filled PBF-a as showed higher thermal and thermal-oxidative stability than

those of CFs filled PBF-a. From SEM (**Fig. 30**) analysis, it was observed that all the FRP composites showed the uniform/homogeneous morphology with well-penetrated fibers with almost zero cavity.

Krishnadevi *et al.* reported the cardanol based PBZ bio-composites using functionalized rice husk ash (FRHA) and cardanol based benzoxazine monomer (CBz) via thermal ring opening polymerization and studied their thermal, electrical, and biological properties (Krishnadevi *et al.*, 2020). The thermal stability of neat CBz matrix, and different weight content of FRHA reinforced CBz bio-composites were studied using TGA and the results obtained are presented in **Fig. 31** and **Table 2**. The $T_5\%$ and $T_{10}\%$ weight loss degradation temperature obtained are 304–319°C and 347–370°C, respectively, for FRHA-filled CBz bio-composites.

The residual char yield increased significantly to 47% for FRHA-filled CBz bio-composites from 12% for neat CBz. This may be due to the inert silica layer of FRHA, which act as the passive protective layer on surface of the CBz bio-composites, and in turn, inhibits the further degradation. Further, the value of T_g are also increased to 145°C for CBz bio-composites from 129°C for neat CBz.

Liu *et al.* reported the preparation of varying weight percentage concentration (0–30 wt%) of silicon nitride (SN) filled PBZ composites via a compression molding (Ramdani *et al.*, 2014). The TGA results shown that the thermal stability of these PBZ composites was greatly enhanced by the introduction of SN filler. Fig. 32 and Table 2 display the TGA results of neat PBA-a and different SN reinforced PBZ composites. As it is evidently observed, the 5 and 10 wt% decomposition temperatures of neat PBA-a are 315 and 338°C, respectively, with the residual char value of 29%. In case of 5 and 10 wt% SN reinforced PBz composites, the decomposition temperatures and char yield values were observed as 329–362°C, 351–394°C and 33%–56% respectively. The introduction of SN nanoparticles into PBA-a matrix ominously enhanced its thermal stability which increased with increasing the percentage weight content of SN reinforcement. This enhancement in thermal properties is owing to the influencing impact of nano-SN in the PBZ that behave as the thermal insulator to protect the PBA-a matrix. The value of T_g of neat PBZ matrix and SN

filled PBZ composites were checked with DMA and the results obtained are depicted in **Fig. 33** and **Table 2**. From the DMA studies, the value of T_g was increased with increasing the weight percentages of SN in to the PBZ. The improvement in T_g was ascribed to the increase of cross-linking density and rigidity. Fractured surface morphology of neat PBA-a and SN reinforced PBA-a composites are studied with SEM analysis and the results are shown in **Fig. 34**. From SEM micrographs, it is clearly realized that the neat PBA-a shows a smooth and unremarkable fractured surface morphology that indicated its brittle in nature. Though, the morphology of its composites at different weight percentage of SN (**Fig. 34(B–F)**) possesses the good and homogeneous dispersion of SN filler in the PBA-a matrix with improved interfacial interaction.

Fig. 33 T_g values (Tan δ) from DMA thermogram of neat PBA-a and PBA-a/SN nanocomposites. Copyright 2014, Reproduced with permission from Ramdani, N., Wang, J., Wang, H., *et al.*, 2014. Alagar research group reported the effect of UV resistant material based on PBz as polymer matrix and variable weight content of (0, 1.0, 3.0, and 5.0 wt%) POSS as filler (Selvi *et al.*, 2014b). The PBZ/EP matrix and composites developed were analyzed using diverse analytical techniques. The values of T_g of OG-POSS introduced PBZ/EP nano-composites are enhanced with increasing the weight content of OG-POSS. Fig. 35 shows the TGA graph of PBZ/EP/POSS composites, the introduction of small amount of OG-POSS (1.0, 3.0 and 5.0 wt%) into the PBZ/EP, there is no considerable enhancement was perceived in the value of $T_5\%$ and $T_{10\%}$ weight loss temperature. While the residual char values is noticeably increased from 21 wt% (neat PBZ/EP) to 34.2 wt% (5 wt% of PBZ/EP/POSS). High residual char value is a valuable information to predict the behavior of flame retardance. This may be owing to the combined influences of higher amount of silica and aromatic groups improved the cross-link density and hinders the dissemination of fragments.

Fig. 36 displays the TEM image of 1.0, 3.0 and 5.0 wt% PBZ/EP/POSS nanocomposites. It can be observed that the OG-POSS materials are dispersed uniformly in the PBZ/EP matrix. No confined domains and no phase separation were perceived even at nanometer scale, suggesting that reinforcement POSS were uniformly dispersed throughout the matrix system and there is no POSS agglomerations has achieved. Data obtained from SEM and tensile studies indicate that the 5.0 wt% POSS filled PBZ/EP nanocomposites satisfy the requirements of UV resistant material.

The same research group reported the cyclophosphazene nanotube (PZT) reinforced poly(benzoxazine-co- ϵ -caprolactam) (P(BZ-co-CPL)) composites in order to enhance the thermal and flame retardant performances (Selvi *et al.*, 2014a). The UL-94 outcomes of P(BZ-co-CPL)/PZT hybrid nanocomposites exhibited V-1 rating, while the neat P(BZ-co-CPL) indicated burning rating. From thermal studies, it was observed that the PZT reinforced P(BZ-co-CPL) composites exhibited better T_g and thermal decomposition performance than those of neat P(BZ-co-CPL). The TEM images determine the homogeneous dispersion of PZT fiber in the (PBZ-co-CPL) matrix. The DSC analysis reveal that the T_g values of neat P(BZ-co-CPL) and PZT filled P(BZ-co-CPL) are 162, 170, 181 and 192°C respectively. The PZT filled P(BZ-co-CPL) composites possess higher T_g values than that of neat P(BZ-co-CPL). This might be owing to the PZT fiber in the P(BZ-co-CPL) rises the rigidity/steric interruption, and constrains the movement of polymer matrix. From the TGA (Fig. 37) analysis it was concluded that the initial $T_5\%$ loss temperatures are 218, 230, 236 and 243°C respectively for neat P(BZ-co-CPL) and PZT (0.5, 1.0, 1.5 wt%) filled P(BZ-co-CPL). The increase in the initial decomposition is owing to the PZT fiber present in the composite system which rises the steric hindrance and high crosslinking network. Similarly, the residual char yield values obtained are 19.8%, 27.2%, 31.0% and 34.8% respectively for neat and PZT filled PBZ/EP systems. The high char may be due to the higher thermally stable PZT fiber in the P(BZ-co-CPL) matrix. The morphology behavior of PZT fiber reinforced P(BZ-co-CPL)/PZT composites was studied with HR-TEM, and the corresponding TEM images are presented in Fig. 38. From TEM images, it was confirmed that PZT were mostly in the form of nanofiber and revealed a fine length dissemination. It was established that the PZT fibers are about 2–6 μ m in length, about 30–50 nm with inner diameter. Further, it can be noticed that PZT nanofibers are uniformly dispersed throughout P(BZ-co-CPL) matrix, which contributes to their good compatibility of PZT fiber and polymer matrix phase result in high thermal and mechanical performances.

Summary

Polymer matrix composites are one of the most economical materials and are used in different fields together with marine, aerospace, construction, sports components, off-shore applications, fire and flame resistant components, waterlines, construction of building and etc., owing to their exceptional processability, lower weight, good crosslinking capability, and outstanding mechanical properties. In this article we discussed the thermal and morphological properties of various polymer matrix

composites especially epoxy matrix, polybenzoxazine matrix and different reinforcements namely glass fiber, natural hemp fiber, basalt fiber, carbon fiber, silicon nitride fiber, carbon nanotubes, PZT fibers, POSS and etc. The present article also discusses the possible applications of the polymer matrix composites. In the upcoming years, mainly in the aerospace and automotive, energy production and other related industries need cutting edge novel polymer composites for high performance, cost competitive processing methods including environmentally friendly fabrication methods. Hence, the emergent interest of the usage of renewable polymer matrices and reinforcement to improve the properties of polymer matrix composites are warranted for widespread range of industrial and engineering applications.

Introduction

In the last decade, by the breakthrough advances in technology, single materials have some difficulties to respond the high expectations of the industry. For this reason, material manufacturers are investigating novel multifunctional materials. In this regard, composite materials offer various possibilities in many different applications. In particular, polymer matrix composites help to the investigators in achieving the asked properties in the existence of proper fillers.

Recently, high thermal conductive composites have a prominent place in microelectronics industry because of miniaturization and increasing power demands. Therefore, generated heat during the operation must be dissipated effectively from the device to maintain the reliability and lifespan [1]. Thanks to its low cost, outstanding electrical insulation property and ease of processing, epoxy resin is an optimal moulding compound for encapsulating heat-dissipating electronic devices. However, heat dissipation capability of epoxy resin should be improved by adding high thermal conductive fillers [2]. Various studies have been realized by altering type of fillers including metal particles (iron, zinc and copper) and ceramic particles (boron nitride (BN), alumina (Al_2O_3), silicon carbide (SiC) and aluminium nitride (AlN)). There are some drawbacks of metallic fillers compared to ceramics such as high density and susceptibility to oxidation. For ceramic particles, BN and AlN are very effective due to their high thermal conductivity. Nevertheless, AlN is affected easily from the moisture whereas BN does not have this disadvantage [3–5]. For this reason, in this study BN and alumina have been used due to their favourable mechanical and thermal properties. As the second reinforcement, alumina has good thermal conductivity, inertness to most acids and alkalis, high adsorption capacity, thermal stability and electrical insulation, and so on. Also, it is inexpensive, non-toxic and highly abrasive [6–8]. More specifically, in this study alumina has been used in fiber form and it has advantages compared to particle form. For instance, the diameter of alumina fiber is about two times larger than that of carbon fiber. Also, another beneficial parameter as interfacial strength and elastic modulus in a radial direction (Young's modulus of alumina fiber is much larger than that of carbon fiber in a radial direction) may also contribute to the strength and fracture mechanisms [9]. Besides, alumina fibers have outstanding compressive strength and shear properties [10].

Although the use of BN to improve thermal conductivity is quite common, hybridization of the matrix with fresh scrap rubber introduces a novelty in this area. Also, rubber particles are thought a good option to reduce the brittleness of the matrix. In addition, the use of fresh scrap rubber adds a value to this study in terms of economic and environmental aspects. For instance, non-used vulcanized scrap rubber causes to costly landfills. Also, in the context of landfilling, due to the impermeability and shape of discarded tires, they hold water for a long while and this creates a habitat for mosquito larvae as well as other animals such as rodents and snakes [11,12]. These may carry infections namely malaria, cephalitis, dengue and chikungunya. Besides, if these piles burst into flames, it is quite difficult to extinguish them [13]. Last but not least, some additives of landfilled tires such as colorants, stabilizers, flame retardants and plasticizers may leach from the bulk of the tires to the soil. Hence, they can harm or kill some beneficial bacterial colony in the soil [14]. For this reason, in this study by recycling of vulcanized rubbers we open a window into the green manufacturing of the multifunctional composites.

This work presents processing of recycled rubbers blended with epoxy resin to create novel composites in economic way. Main objective of this research is to determine the mechanical and physical properties of these composites. During this study, physical properties such as glass transition temperature and phase transitions are determined with dynamical mechanical analysis (DMA) and differential scanning calorimeter (DSC). Then, bending tests are realized with smooth specimens. After that, nano indentation tests are examined to see the time dependent behaviour and wear characteristics. In addition, surface hardness is determined by means of Shore D hardness measurement and macro wear characteristics are evaluated by means of scratch test. At the end, fracture surfaces are observed by means of scanning electron microscopy (SEM) to study the toughening and damage mechanisms.

Experimental Conditions

Materials Processing

The use of recycled rubbers in a composite system is more complicated than general belief for various reasons. Due to the former vulcanization process, cross-linked structure of rubber limits the movement of rubber chains and restrain the interaction forces between epoxy matrix and scrap rubber particles. For this reason, a decrease in the performance of final product is observed

[15–17]. In this case, in order to improve materials properties of the final product, devulcanization operation is recommended. According to ASTM definition, devulcanization is “a combination of depolymerization, oxidation and increased plasticity” since during reclamation each of these processes generally occurs. *In fact*, the reverse of the vulcanization can be named as devulcanization [18]. During sulphur vulcanization, C–S and S–S bonds are generated. On the other hand, in an ideal devulcanization process, it is expected only C–S and S–S bonds cleavage without any degradation on the main-chain. Devulcanization occurs if the provided energy is higher than the link energies of monosulfidic C–S (270 kJ/mol) and polysulfidic S–S (240 kJ/mol) bonds without exceeding that of peroxide C–C (345 kJ/mol) bonds. In the frame of the present work, the energy for devulcanization is provided by microwaves and it is followed by chemical surface treatments. This combined method contains exposing recycled rubbers to microwave heating in a short time followed by a pre-chemical treatment that is applied in practical point of view. By this way, a good cohesion is supplied at the interface between epoxy resin and rubber powders to improve the properties of the recycled rubber (SBR with a particle size varying from 30 to 130 μm) coming from the sportive equipment. It means that they are fresh, clean and completely different from ground tire.

First, recycled rubbers are exposed to short microwave heating during 4 min in order to avoid degradation of the main chains. Then, chemical treatment is applied. The principal of the chemical treatment consists in a short silanization process followed by acrylic acid and a small amount of toluene solution to activate the surface of the rubber particles. After drying of the chemical treated rubber powders, at the final stage, devulcanized rubbers are mixed with epoxy resin powders. This mixture is used as a matrix of the new composites then, the new designed composites are manufactured by using classical powder metallurgy methods. After the mixture of the reinforcements (BN, alumina fiber and SiC) in the matrix, milling process is carried out during 4 h.

Subsequent to having a homogeneous powder compound, the composite specimens are manufactured by using double uniaxial action press at a temperature of 180°C under a pressure of 70 MPa during the heating of 30 min. All of the specimens (30/50 mm in diameter) are cooled slowly in the press. All of the specimens are post-cured isothermally at 80°C for 24 h. This procedure is illustrated in Fig. 1.

The compositions designed for two types of the composites in this work (hereafter called as EBNA I-II-III) are given in Table 1.

Thermal Analyses and Physical Characterization

Differential scanning calorimeter (DSC) analyses are performed on DSC Q10N2 apparatus of TA Instruments, USA, from – 80 to 400°C in air flow with a 1 dm³/min flow rate and heating rate of 10°C/min.

Dynamic properties, storage modulus (E') and mechanical loss angle tangent ($\tan \delta$) of the epoxy based composites are investigated using a Dynamic Mechanical Thermal Analyser Q800 system (TA Instruments). The data are obtained at a frequency of 1 Hz, 0.1% strain in the temperature range from – 80 to 200°C using a heating rate of 3°C/min under single cantilever bending mode. The dimensions of the investigated samples are as follows: width 10 mm, length 30 mm, and the thickness 3 mm.

Microscopical Observation and Three Point Bending Testing

Microstructure and fracture surface damage analyses have been carried out by means of optical (OM) and scanning electron microscopy (SEM). SEM observation is realized on fracture surface of the tested specimens with Scope/JSM-6010LA Jeol® electron microscope.

After post curing, hardness measurements on the specimens are performed. Shore D hardness test measurements on the polished flat surfaces of the specimens are carried out according to ASTM D 2240 using Shore D hardness tester, (type HBD-100-0).

Three-point bending tests (3PB) have been carried out according to the ASTM D790 standards. Deflection of the specimen is measured by the crosshead position and crosshead speed is selected as 1 mm/min. Flexural strength and strain are obtained from the test results. The test specimen is placed to the Instron 5569 bending test machine's supports and force is applied until it breaks. At least three specimens for each composition are used and standard deviation and average values are given in results article with standard deviation values.

Nano-Indentation Analyses by Means of Creep and Wear Tests

Creep tests using a nano-indenter are performed on the two compositions manufactured to see the time dependent behaviour. On each sample 20 indents are performed on a 5 × 4 grid with a Berkovich indenter. The indents are spaced 50 μm along the 5-indent side and 75 μm along the 4-indent side. The load is increased at a rate of 1 mN/s to the max load and kept at the maximum load for 500 s then unloaded.

Scratch testing capability of a nano-indenter is utilized to perform relatively fast wear tests to compare the wear behaviour of the different samples. Wear tests are conducted by a conical tip with a 90° cone angle. Tests are run under a normal load of 20 mN applied over a linear track of 500 nm for 50 cycles.

Damage Analysis by Means of Scratch Test and 3D Optical Roughness Meter

Scratch tests results give a basic idea on the tribological behaviour of the epoxy and recycled elastomer-based composites designed in the current research. After the scratch test, damage zone is investigated by a 3D optical surface scanner to assess damage in terms of scratch depth and average scratch roughness.

Fig. 1 Manufacturing of recycled rubber modified epoxy-based composites.

Table 1 Composition of the epoxy-rubber based composites

<i>Epoxy-Rubber based composition</i> <i>Epoxy – SBR rubber (10 phr)</i>	<i>EBNA I</i>	<i>EBNA II</i>	<i>EBNA III</i>
Reinforcements (wt%)	5 Al ₂ O ₃ fiber 5 Boron nitride 1 Silicium carbide	5 Al ₂ O ₃ fiber 10 Boron nitride 1 Silicium carbide	10 Al ₂ O ₃ fiber 5 Boron nitride 1 Silicium carbide

In the scratch test the contact between the sliding diamond indenter and the surface of the composite material is analyzed. The normal and tangential forces on indenter are recorded and the tangential stress on the surface and the interfacial stresses can be obtained.

In the frame of this present work wear resistance is evaluated only under dry conditions and 50,000 and 100,000 number of cycles of wear for the composites presented here.

In the frame of the current research, the resistance to scratch deformation is evaluated in terms of scratch depth, surface and worn volume subsequent to scratching.

Results and Discussions

Microstructure of the Composites

In [Fig. 2](#) two different specimens are shown in different diameters for different characterizations. They are manufactured by means of hot compaction technics.

General microstructures of one of the compositions are shown in [Fig. 3](#). All of the compositions showed a considerably homogenous distribution of the reinforcements in the microstructure. Essentially, it is seen that the adhesion of the rubber to the epoxy matrix is very successfully carried out after the chemical treatment. In addition, white circular particles show the alumina fibers in different sizes. Some small local agglomerations of rubbers are observed in the microstructure due to the incomplete mixture process. Because, homogenous distributions of the reinforcements need more mixture process.

After microstructure observations, Shore D hardness results are given in [Table 2](#).

From [Table 2](#) it is seen that BN particles are increasing the surface hardness better than alumina fibers.

Fig. 3 Microstructure of a specimen EBNA II in low (left) and high magnification (right) showing interface of rubber with epoxy.

Thermal Analysis and Physical Characterization

After all blending and material preparation processes, DSC analyses are realized on unpolymerized powder compositions and the results are given in **Fig. 4**. From thermo-gram of DSC, it is seen that curing started slightly above the room temperature and it finished around 180°C . Also, in the same thermo-gram it can be indicated that physical and/or chemical reactions occur intensely around 240°C and they are thought as possible oxidations over 200°C [19].

After DSC analyses, fundamental idea on elastic response and viscous response of the material are obtained respectively from storage modulus (E') and loss modulus (E'') under dynamic loading. Then, the loss factor ($\tan \delta$) is determined by taking the proportion of loss modulus to storage modulus which is a measure of the energy lost from the material under loading at different temperatures. It shows the internal friction or mechanical damping in a viscoelastic material [20]. After acquiring the results, T_g can be determined by taking the first inflection point, or the onset of the drop-in storage modulus. However, the simplest approach to determine T_g is taking the peak of $\tan \delta$ [21].

DMA analysis is important for the manufactured composites. Because, the determined glass transition temperature can be thought as a temperature limit for the structural applications. Because, mechanical resistance of these composites drops drastically after T_g and this should be considered during design process.

Fig. 5 exhibits the $\tan \delta$ and storage modulus at different temperatures for different compositions. T_g of these composites are determined between 117 – 128°C and it is seen that ascending boron nitride rate increases the T_g of these composites. From this situation it can be said that boron nitride particles lower the polymer chain mobility. Hence, BN content dominant composites remain in the elastic region for a longer wider temperature range than other compositions [22]. However, increasing amount of alumina fibers (EBNA III) promotes more energy dissipation from the material compared to (EBNA II) and it dominates the increase in the storage modulus. In addition, lower E' values under T_g gives an indication about more flexible structure of the EBNA I composites. Also, **Fig. 6** presents Cole-Cole plot where E'' data are plotted as a function of E' for EBNA composites. The shape of the Cole-Cole plots is stated to be designative of the homogeneity of the composite system. Semicircle curve demonstrates that polymeric system is homogeneous [23]. It can be seen that increased amount of BN particles alters the shape of Cole-Cole

Table 2 Hardness values of EBNA specimens

Hardness measurement	
Specimen	Shore D
EBNA I	88
EBNA II	93
EBNA III	89

plot. For EBNA I and III compositions the Cole-Cole plot is warped semicircular, whereas for EBNA II it is quasi-round in shape. Warped semicircular suggests that there is heterogeneity among the matrix and the fibers. It is concluded that amount and shape of fillers influence the shape of Cole-Cole plot by affecting dynamic mechanical properties of these composites [24,25].

Three Point Bending Tests and Fracture Surface Observation

Three-Point Bending (3PB) tests have been carried out for each different type of composites.

Flexural stress is calculated during three-point bending test according to the Eq. 1:

$$\sigma = \frac{3Pl}{2bh^2} \quad (1)$$

In this formula, l is the span length, P is the maximal bending load, b and h are the sample thickness and depth, respectively. Flexural strain, ε_f , is determined according to the Eq. 2:

$$\varepsilon_f = \frac{6Dh}{l^2} \quad (2)$$

D is the maximum deflection at the center of the specimen.

E_B is the modulus of elasticity in bending and it is expressed with the Eq. 3 as follows:

$$E_B = \frac{l^3 m}{4bd^3} \quad (3)$$

m is the tangent of the initial straight portion of the stress-strain curve.

Fig. 5 Evolution of storage modulus as a function of the temperature for three EBNA specimens.

Fig. 6 Cole-Cole plot for EBNA composites.

From [Table 3](#), one can comment that alumina fibers are more efficient to increase the flexural strength and modulus compared to boron nitride. Also, excessive amount of boron nitride particles has detrimental effect on modulus values. This situation is commented as the existence of agglomerated BN particles behaves as stress concentrators. On the other hand, modulus and strength values for the matrix show considerably large standard deviations. Therefore, important fluctuations between different specimens are observed. Despite the increasing trend at strain values, matrix is seen still more flexible than the composites. However, more precise determination requires fracture toughness calculations with notched specimens.

After 3PB tests, SEM observation is done on fracture surfaces. [Fig. 7](#) shows the fracture surfaces of EBNA I-II-III composites in different magnifications. As first impression, it can be commented that rough fracture surfaces give a sign about the good adhesion between matrix and reinforcements. Also, the fibers which are perpendicular to fracture surface created a link (crack bridging in

Fig. 10 Comparison of wear track deformation for EBNA composites.

Fig. 6(a) inside red circle) between two sides of the crack and it has a positive effect against to crack opening. In recycled rubber modified epoxies the main toughening mechanism is thought as crack deflection with the secondary contributions of shear deformations [26] but here important mechanism is attributed to crack blunting (in **Fig. 6(b)** inside red circle) by a hard particle as well as bridging effect of fibers.

3.4 Time Dependent Behaviour by Means of Nano-Indentation

During each test, data collected is used to calculate the creep compliance and the stress exponent defined in Eq. 4 [27]:

$$\varepsilon(t) = \sigma_0 J(t) \quad (4)$$

where σ_0 is the constant stress applied and $J(t)$ is calculated using Eq. 5:

$$J(t) = A(t) / (1 - (v)) P_0 \tan \theta \quad (5)$$

In Eq. 5 $A(t)$ is the contact area, P_0 constant applied load, θ is the effective cone angle which is 70.3° for a Berkovich indenter and the Poisson's ratio V is assumed to be 0.3. This approach takes into account how the contact area under the Berkovich tip alters while displacement into the surface changes.

The strain versus time behaviour during creep is characterized by a high strain rate $\dot{\varepsilon} = d\varepsilon/dt$ in the primary stage of creep and then in the secondary, steady state stage of creep, the strain rate is given in Eq. 6 can be written as:

$$\dot{\varepsilon} = K \sigma^n \quad (6)$$

where K is a constant and n is the stress exponent. The strain rate is calculated in the software and in turn n is obtained from the log-log plot of strain rate versus stress in the secondary stage of creep.

The materials under consideration are heterogeneous in nature and the fact that the nano-indentation test is carried out over a small area/volume, a large scatter in the data is observed and to overcome this sampling number is taken as large as possible then **Fig. 7** is plotted from the average values.

According to **Fig. 8**, creep compliance is improving with the increasing amount of alumina fibers which means that EBNA III has a higher capacity to flow in return to an applied stress [28,29]. Also, the creep compliance is obviously dependent on the indentation forces between 20 and 50 mN.

Besides, the trends in the compliance values with time seem alike for different force levels examined with Berkovich tip, and this implies dissimilarity of the time-dependent behaviour from stress-dependent behaviour [30].

Results may be compared with linear viscoelastic models. However, these models do not consider the case of tip-specimen adhesion which may differ from experimental results.

From **Fig. 9(b)** it is seen that, increasing BN amount results in an increase in the stress exponent which means that viscoelastic characteristic of the material is improved. On the other hand, by the increase in the reinforcement rate modulus is not improved as in the 3PB testing as seen in **Fig. 9(a)**. For this reason, these values should be compared with the values obtained from the other methods.

Whether or not indenter tip comes across a BN rich zone or a matrix rich area on the specimen will introduce error into this method. Hence, whilst the amount of BN increases, the error bars become larger. Different researchers have indicated for polymers and polymer-based composites that modulus as determined by nano-indentation is higher than that determined by macroscopic tensile tests. This inequality is thought as a consequence of pile up of material around the contact impression and viscoelasticity of

Fig. 11 Three-dimensional damage traces obtained in the direction of width and length for (a) EBNA I (b) EBNAII (c) EBNA III for 50 k cycles and for 100 k cycles.

Fig. 12 Worn surface and worn volume after scratch tests.

the polymer and polymer based composites which are not taken into consideration during the modulus determination by the Olivier-Pharr method [31].

Wear Testing by Nanoindentation

Last but not least, nano-indenter is used to obtain scratches over the specimen. One cycle is defined as a pass and return of the indenter over the track, so the total distance covered for one wear test is 0.050 m. Speed of the tip during wear tests is 50 $\mu\text{m/s}$.

Total of 10 wear tests for each specimen are performed under the two normal loads. The wear in a track is characterized as the area between the initial profile and the residual profile of the wear track.

In the same way, the averages of the wear track deformation are shown in Fig. 10.

Increase in alumina fiber content result in higher surface deformation in nano scale. However, to comment properly on wear resistance, lost volume and damaged surface evaluation after tests is considered more trustworthy. For this reason, macro scratch tests are realized to see the more accurate wear resistance.

Damage Analysis by Means of Scratch Test and 3D Optical Roughness Meter

After realizing two different group of macro scratch tests, three dimensional damages are obtained by a 3D optical surface scanner. The results are presented in the Fig. 11.

In Fig. 12 the volume and surface of the damage trace after scratch calculated from roughness test results are given. Fig. 12 indicates that thanks to the hard nature of BN particles, EBNA II composites have less damage. Hard particles provide a more wear resistant material upon homogeneous distribution. In reality, because of the high shear stress at the interfaces the interfacial shear stress should probably be the main reason for damage of the matrix and reinforced filler interfaces. When the indenter is slipping, tangential tensile stress is caused on the surface behind the indenter, while in front of the indenter the tangential stress is compressive.

Conclusions

After manufacturing of epoxy-recycled rubber based composites, microstructure is observed with SEM. From the images, a homogeneous distribution of the reinforcements is observed. However, in minor scale certain agglomerations of rubbers is detected. This situation arises from limited milling duration. On the other hand, there is a risk of degradation in properties if the milling time is kept excessively long.

Second, alumina fibers are found more efficient than BN to improve the mechanical strength. However, the flexibility of material decreases by the addition of reinforcements. In addition, modulus values obtained from nano indentation, differ from the macro test results. This is considered as a consequence of pile up of material around the contact impression and viscoelasticity of the polymer. Furthermore, creep compliance values presented that alumina fibers provide a higher capacity to flow in return to an abruptly applied stress.

Another important point is that, BN particles have increased the T_g of the composites whereas alumina fibers did not influence it noticeably. This indicates that alumina fibers do not affect the polymer chain mobility as much as BN.

In addition, scratch test results showed that BN particles are efficient against to wear thanks to its hard nature. Last but not least, after mechanical tests, fracture surfaces are observed by means of SEM to identify toughening mechanisms. Crack deflection and crack blunting with the contribution of fiber bridging are thought as the main toughening mechanisms.

By considering all material characterization results, these novel composites can be used in micro electric industry as component base material thanks to their advantageous properties in mechanical and thermal aspects.

Introduction

Graphene (Gr) is a two-dimensional material having remarkable properties like high Young's modulus, ability to be thermally and electrically superconductive (high mobility of charge and electron), surface insulating behavior, and large aspect ratio for prototype fabrication. Graphite is a low-cost raw source for extraction of Gr. The Gr is generally extracted via different methods of processing, such as chemical vapor deposition (CVD), micromechanical exfoliation, ball milling, etc. (Park and Ruoff, 2009; Su *et al.*, 2011; Calderon-Ayala *et al.*, 2017). The previous studies reveal that the exfoliation process can also be used for chemical processing of graphite in water for Gr production using 1-pyrenesulfonic acid sodium salt (Yang *et al.*, 2013). Graphite is the best and most economical source for the extraction of Gr material. The literature review highlights that the oxidative treatment of graphite resulted in formation of graphite oxide (GO) for extraction of Gr (Hummers and Offeman, 1958; Mao *et al.*, 2012). The oxidation and exfoliation mechanisms for GO production were explained by Shao *et al.* (2012), Lopez *et al.* (2016), and Monajemi (2017). Synthesis of Gr through exfoliation of natural graphite in ortho-dichloro benzene (ODCB) has been achieved by a process called "sonication," (Sahoo *et al.*, 2013). All Gr extraction techniques contributed to achieve specific mechanical, optical, and thermal properties, as CVD led to Gr sheet production with high mechanical strength (Choi *et al.*, 2010; Zhao *et al.*, 2016). A highly sensitive behavior of Gr in terms of thermal and electrical conductivity made it eligible for its applications in fabrication of biosensing devices, electronic circuit charge storage devices, and medical biosensors (Irudayaraja, 2012; Obeng and Srinivasan, 2011; Hantel, 2013). This excellent material behavior of Gr extracted from graphite has been best applicable to the three-dimensional (3D) printing (fused deposition modeling, FDM) of components for high quality sensors, medical devices, and precision mechanical and electrical tools. FDM has emerged as a revolution in the field of additive manufacturing (AM) where one can fabricate complex 3D structures. FDM setup requires a .STL file format of 3D geometrical shape prepared on software. These geometrical .STL files are further mathematically oriented and sliced for prototype fabrication (Liou, 2008; Kumar *et al.*, 2012). Fig. 1 shows two spools of feedstock filament (i.e., support and build material) fed through a heating arrangement to provide molten deposition through the heater nozzle. The heater nozzle moves in the direction as geometrical shapes are oriented and sliced through G-code and M-code.

Most of the studies related to the FDM process applications highlighted the preprocessing and postprocessing of prototypes (Nunez *et al.*, 2015; Equbal and Sood, 2015; Goyanes *et al.*, 2015; Singh and Singh, 2015; Srivastva *et al.*, 2015). FDM has emerged as a specific tool for analysis by fabricating functional prototypes (Guerrero-Villar *et al.*, 2015). It has been reported that FDM technology covers almost every area of application. For example, in the medical field, a device oral pulsatile for release of drugs and patient-tailored tablet has been fabricated by FDM (Skowrya *et al.*, 2014; Melocchi *et al.*, 2015). In this article, a systematic procedure for extraction of low-cost Gr followed by development of feedstock filaments for FDM has been outlined as a case study. The thermal and electrical conductivity analysis of Gr-blended acrylonitrile butadiene styrene (ABS) polymer matrix has been performed on in-house developed feedstock filament for fabrication of functional/nonfunctional prototypes.

Materials and Method

Materials

Low-cost Gr-blended feedstock filament can be prepared through use of graphite powder. Commercial ABS polymer and graphite micropowder was procured from the local market. Graphite micropowder was processed by sieve shaker to know grain size for the purpose of Gr extraction. The ABS granules were pretreated in an oven at 70–80°C temperature for moisture removal.

ABS is an amorphous polymer that is made by polymerization of acrylonitrile and styrene in presence of catalyst polybutadiene. Acrylonitrile, which contributed 15–35%, improves cross-linking butadiene and styrene; butadiene, which contributed 5–30%, polarizes and forms long carbon chains; and styrene, which contributed 40–60%, has opaque and smooth surface properties. ABS polymer has thermal conductivity 0.1 W/m K, glass transition temperature approximately at 105°C, and no true melting point because of its amorphous nature (Matbase, 2014; ABS Prospector, 2016). Graphite is semimetallic characterized allotropes of carbon, which is available in crystalline form and is considered to be the most stable form of carbon. Graphite is an economical source for extraction of Gr powder by various physical and chemical methods. Metamorphism with the reduction of sedimentary carbon helps for the occurrence of graphite in the rock form. Quartz, calcite, and micas are some of the minerals that

Fig. 1 Schematic of fused deposition modeling (FDM) technique. Reproduced from Kun, K., 2016. Reconstruction and development of a 3D printer using FDM technology. *Procedia Engineering* 149 (1), 203–211.

are naturally associated with graphite as foreign particle. According to surveys conducted by United States agencies, China, and India are the major producers of graphite. Graphite has the excellent properties of high thermal stability, remarkable electrical and thermal conductivity due to charge and electron mobility, good machining characteristics, and toughness.

ABS polymer matrix filled with graphite generally reduces wear as the coefficient of friction becomes smaller. Graphite as reinforcement to ABS polymer matrix led to reduction of mechanical strength and weight (see Fig. 2).

The mechanical properties of ABS polymer matrix filled with graphite are less than the parent material. But Gr extracted from graphite improves the ABS polymer matrix and their mechanical properties are much greater than the parent ABS plastic. The addition of carbon nanotube (CNT) and Gr in ABS matrix as a filler improves the thermal and electrical conductivities (Wang *et al.*, 2015). Figs. 3(a) and (b) show that electrical conductivity of ABS matrix was increased as CNT contents increases and at 0.06% CNT level the *V-I* characteristics were obtained as desired.

Various studies have been conducted to investigate the effect of Gr content incorporated into the polymer matrix. In a study conducted by Dul *et al.* (2016), an effect of heat flow rate has been observed for compression molded (CM), extruded (E), and 3D printed (H) natural ABS and ABS-4% Gr composites. Fig. 4 shows that 3D printed parts with 4% Gr contents achieved maximum heat flow.

Method and Procedure

Extraction of Gr for development of feedstock filament for FDM

Exfoliation is a chemical approach for removal of GO from graphite dissolution to achieve Gr extraction (Sahoo *et al.*, 2013). The exfoliation process forms chemically converted stable Gr from graphite powder with much lower production cost (Eda *et al.*, 2008; Xu *et al.*, 2008; Li *et al.*, 2008). Fig. 5 shows the process of exfoliation through which feedstock filaments are developed for 3D printing. In this case study a 3D printed part has been used as a specimen for thermal analysis by standard Lee's disk method.

Some common organic chemicals (e.g., benzene, toluene, nitrobenzene) have been reported for use as catalyst for chemical exfoliation of graphite. Further *N*-dimethyl-formamide (DMF) and *N*-methylpyrrolidone (NMP) have been used to form homogeneous dispersion of Gr (Niyogi *et al.*, 2003; Blake *et al.*, 2008; Hernandez *et al.*, 2008; Hamilton *et al.*, 2009). Except chemical exfoliation some studies have been reported for exfoliation through electrochemical, water dispersion and other mode of dispersion (Su *et al.*, 2011; Yang *et al.*, 2013; Zhou *et al.*, 2014; He *et al.*, 2015; Sharma *et al.*, 2015). The detailed procedure has been shown in Fig. 5. The mixing of graphite in organic solvent contributed to the mixing of graphite dissolution. Further the treatment in ultrasonic bath followed by centrifugation provides separation of graphite flakes from Gr. The aging of Gr dissolution contributed to the stabilization of Gr layers in solution. After this the graphite flakes are removed to extract the Gr through pipetting. The Gr is further mechanically blended with ABS granules for the preparation of feedstock filament by twin screw extrusion process. Finally the prepared feedstock filaments were fed to the commercial FDM setup for preparation of 3D parts (in disk shape) to be used for thermal and electrical analysis.

Experimentation

Initially the pilot experimentation was conducted for extraction of Gr through exfoliation of graphite flakes with naphthalene powder in NMP solution under experimental conditions suggested in Fig. 5. The unexfoliated layer was considered as extracted Gr from graphite dissolution. Extracted Gr was then mechanically mixed with ABS granules to blend and extrude through the twin screw extruder. The feedstock filament has been prepared by twin screw extruder under maintained input process variables, and was fed into commercial FDM (3D printer) to fabricate a disk shape pattern for thermal and electrical analysis.

Fig. 2 Effect of graphite content on (a) mechanical strength, (b) coefficient of friction, and (c) weight loss. Reproduced from Difallah, B.B., Kharat, M., Dammak, M., Monteil, G., 2012. Mechanical and tribological response of ABS polymer matrix filled with graphite powder. *Materials & Design* 34 (1), 782–787.

Gr Extraction

Chemical exfoliation of graphite powder has been performed with chemical mixing of graphite with naphthalene powder in NMP solution followed by holding in ultrasonic bath for 90 min at 50°C and centrifugation for 60 min at 2000 rpm at room temperature. Continuous aging for 24 h has contributed to the separation of Gr layer from graphite flakes. Pipetting was performed to collect the Gr layer as to separate the graphite flakes. [Fig. 6](#) shows the Gr extraction by exfoliation process.

Twin Screw Extrusion

After mechanical mixing of ABS granules with extracted Gr from chemical exfoliation process, extrusion has been performed to achieve feedstock filaments. Thermo Scientific HaaKE MiniCTW microconical twin screw compounder has been used for feedstock filament preparations. [Fig. 7](#) shows a schematic of the twin screw extruder setup.

Fig. 3 (a) Thermal conductivity with varying carbon nanotube (CNT) proportions. (b) Current-voltage relationship for 0.06 vol% CNT/ABS nanocomposite. ABS, acrylonitrile butadiene styrene. Reproduced from Al-Saleh, M.H., Al-Hamid, H.K., Hussain, Y.A., 2013. CNT/ABS nanocomposites by solution processing: Proper dispersion and selective localization for low percolation threshold. Composite: Part A 46 (1) 53–59.

Fig. 4 Effect of Gr contents on compression molded (CM), extruded (E), and 3D printed (H) parts of acrylonitrile butadiene styrene (ABS). Reproduced from Dul, S., Fambri, L., Pegoretti, A., 2016. Fused deposition modeling with ABS-graphene nano composites. Composites: Part A. Available at: <https://dx.doi.org/10.1016/j.compositesa.2016.03.013>.

The pilot experimentations have been performed for different level of screw speed, screw temperature, and applied load conditions. On the basis of uniformity and dimensional accuracy achieved, the input process parameter has been selected as shown in Table 1.

Based upon input parametric conditions as per Table 1, a fixed proportion/composition of ABS-Gr has been fixed as 75:25 (by weight). Fig. 8 shows the extruded filament of ABS-25Gr.

FDM (3D Printing)

An .STL file extracted from designing software has been fed through the FDM setup for disk fabrication. The .STL file is sliced through Repetier-Host V0.95F software at the desired geometrical orientation and angle. The FDM setup consisted of two nozzles, one for deposition of base material and another for built part. Both nozzles are assisted with heating arrangement to melt the polymer feedstock filament.

The prepared feedstock filament was passed through the heating chamber at the desired processing conditions as shown in Table 2 to fabricate the disk part.

Fig. 9 shows Gr-blended polymer based disk prepared through FDM process illustrated in this work.

Fig. 5 Procedure for development of low-cost Gr-polymer blended in-house filament for fused deposition modeling (FDM). ABS, acrylonitrile butadiene styrene.

Fig. 6 Gr extraction by chemical exfoliation.

Discussion

Followed by experimentation, fabricated 3D part of disk pattern was then tested to check the effect of Gr on thermal and electrical conductivities.

Thermal Analysis (Lee's Disk Theory for Thermal Conductivity Calculation)

The disk of ABS-25Gr was fabricated on the FDM setup. Thermal analysis of the prepared disk was performed with Lee's disk method. This method for thermal analysis requires thickness and radius measurement of sample, heating arrangement for water

Fig. 7 Schematic of twin screw extruder.

Table 1 Process variables and their level for extrusion

<i>Input process variable</i>	<i>Operating condition</i>
Screw speed	100 RPM
Screw temperature	250°C
Applied load	10 kg

heating, and a set thermocouple for measurement of temperature differences. **Fig. 10** shows the experimental setup for thermal analysis.

As the experiment is conducted for thermal analysis, the following input has been measured:

$$\text{Steady temperature of steam chamber } (t_1) = 367\text{K} \quad (1)$$

$$\text{Steady temperature of Lee's disc } (t_2) = 337\text{K} \quad (2)$$

$$\text{Mass of metallic disc } (M) = 0.769 \text{ kg} \quad (3)$$

$$\text{Specific heat capacity of Lee's disc } (S) = 377 \text{ J/kg K} \quad (4)$$

Table 2 Fused deposition modeling (FDM) process parameter and level for part fabrication

Process variable	Operating condition
Nozzle diameter	0.3 mm
Filament diameter	1.75 mm
Layer height	0.4 mm
Perimeter	3
Solid layers	Top-3; bottom-3
Fill density	0.8
Fill pattern	Honeycomb
Perimeter speed	30 mm/s
Infill speed	60 mm/s
Travel speed	130 mm/s
Extruder temperature	250°C
Bed temperature	55°C

**Fig. 9** View of commercial fused deposition modeling (FDM) setup and fabricated disk.

$$\text{Thickness of 3D printed disc sample } (x) = 0.0074 \text{ m} \quad (5)$$

$$\text{Area of sample } (A) = 0.034 \text{ m}^2 \quad (6)$$

$$\text{Temperature gradient } (dt/dT) = 3.663 \text{ K/s} \quad (7)$$

$$\text{Thermal conductivity of sample} = \frac{MS \left(\frac{dt}{dT} \right) x}{A(t_1 - t_2)} \quad (8)$$

Putting values of Eqs. (1–7) in Eq. (8)

$$= \frac{0.769 \times 377 \times 3.633 \times 0.0074}{0.034 \times 30}$$

Thermal conductivity (K) = 7.6 W/m K

Electrical Conductance Measurement

Electrical conductance (G) was calculated by evaluating potential difference (V) and current transferred (A). The resistance was measured using Ohm's law.

Fig. 10 Thermal conductivity measurement by Lee's disk method.

According to Ohm's law,

$$R = \frac{V}{I} \quad (9)$$

As potential difference measured, $V=2.2$ V and current, $I=5.3$ A.

Putting the values of V and I in Eq. (9), electrical resistance was calculated as,

$$R = 0.415 \, \Omega \quad (10)$$

Following the relationship between electrical conductance (G) and electrical resistance (R), the value of electrical conductance was calculated as,

$$G = 1/R \quad (11)$$

Putting the value of R in Eq. (11), it was obtained, the electrical conductance $G=2.41$ S (Seimens)

Concluding Remarks

An experimental study has been conducted for development of low-cost Gr-blended feedstock filaments of FDM followed by thermal and electrical analysis. The following observations have been made:

At lab level during graphene extraction, it was noted that from 1 kg of graphite powder approximately 20 g of graphene has been extracted. Hence it can be summarized that the chemical exfoliation process is a low-cost method for graphene extraction from graphite powder. This has led to production of low-cost feedstock filament for fabrication of functional/nonfunctional prototypes on commercial FDM setup. The thermal conductivity of natural ABS plastic was 0.01 W/m K and for ABS-25Gr 7.6 W/m K. Thermal conductivity of ABS-25Gr was calculated 76 times more than natural ABS. The excellent thermal and electrical conductivity changes of polymer matrix can lead to its application in low-cost sensors.

Acknowledgments

The authors are highly grateful to Manufacturing Research Lab (MRL), Department of Production Engineering, Guru Nanak Dev Engineering College, Ludhiana (India) for providing financial assistance to carry out the research work. The authors are also grateful to Mr. Gurleen Singh (Research Scholar, MRL Lab) and Mr. Puran Singh for fabrication of 3D parts.

This is a reproduction of Sudhir Kumar, Rupinder Singh, Tajinder P. Singh, Ajay Batish, PLA Composite Matrix as Functional Prototypes for Four Dimensional Applications, In Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2019, doi:10.1016/B978-0-12-803581-8.11595-4.

Introduction

Three-dimensional (3D) printing also commonly known as additive manufacturing (AM) was commercially introduced in late 1980s. This is used to print 3D models of intricate designs. Significant studies have been reported on development of various 3D printing techniques but still lot of research in these technologies is required for making 3D technologies more cost effective (Khoo *et al.*, 2015; Kumar *et al.*, 2018). Product development cycle, less human interaction, and easy production of intricate models at low cost and value-added products are the major advantages in 3D printing techniques (Wong and Hernandez, 2012). 3D printing is yet not fully accepted technique for manufacturing especially for mass production but scientists, researchers, artists, medical practitioners use this technique for various applications (Flowers and Moniz, 2002; Noorani, 2006; Singh *et al.*, 2019). Metal powders, thermoplastics, natural fibers, reinforced matrix of polymers and various composites are some generally used materials for 3D printing (Tofail *et al.*, 2018).

Fig. 1 gives the various processes in AM which is basically categorized for liquid base, solid based, and powder based technologies (Kruth, 1991).

AM used for printing polymeric components can give better alternatives in the following manners (Ligon *et al.*, 2017):

- Low cost component production.
- Low weight components manufacturing.
- Easy production of intricate designs.
- Easy modifications in dimensions of components.

Study reveals that PLA itself behaves as smart material when worked near to its glass transition (T_g) temperature and is used as smart fiber when reinforced with nylon fibers for textile industry. Melt blown technique have been used by researcher to prepare composite of PLA and Fe_3O_4 (Leist *et al.*, 2017). Fig. 2(a) and (b) shows that addition of Fe_3O_4 to PLA does not alter the T_g of PLA but shifts the cold crystallization temperature to the positive side (Yu *et al.*, 2017).

Their results have also shown that when iron oxide is mixed and product is prepared the resulted product holds some amount of magnetic property in compare to neat PLA. Though the magnetic properties obtained via vibration sample magnetometer (VSM) testing were very less. Fig. 3 shows the hysteresis loop of PLA and Fe_3O_4 which shows that the composite behaves as paramagnetic composite.

4-D Printing

4D (4-dimensional) printing is not a new technique of printing but is an expansion of 3D printing. "Time" is the 4th dimension which is added to the previously known 3D printing technology. External triggering using some atmospheric change such as electric field, magnetic field, osmosis based actuation, and light based actuation etc. Thus in this technique of printing, a new composite filament is printed using FDM and the obtained product when triggered with some stimulus such as temperature, magnetic field, humidity and electric field, etc can changes its property respectively. This ability of changing shape and property at some future point of time after solidification of composite crystals comes from the highly engineered molecular spatial distributions and micro molecular smart reinforcement (Li *et al.*, 2016).

Types of 4-D printing

4-Dimensional printing may be defined as a printing of smart material which can respond to some external or internal stimulus at some required time of application. This response of component can be categorized in two types autonomous (without any external stimulus) and non-autonomous (with the help of external stimulus). Recently smart materials are one of the most important research area in which researchers are exploring. These smart materials can be used for 3D printing replacing the usual materials of printing. Thus incorporation of these smart materials in 3D printing is known as 4D printing which can be used to print various smart products. Once the fabricated product gets solidified as 3D object it can respond to external stimulus by using human interference that results in change of shape or physical properties over time (Khoo *et al.*, 2015).

Smart Materials

Smart materials can be of three types

Fig. 1 3D printing processes. FDM: Fused deposition modeling, LENS: Laser engineered net shaping, SLS: Selective laser sintering, SL: Stereo lithography, EBM: Electron beam melting, LOM: Laminated object manufacturing. Reproduced from Kruth, 1991. Material increase manufacturing by rapid prototyping techniques. CIRP Annals 40 (2), 603–614. doi:10.1016/s0007-8506(07)61136-6.

Fig. 2 Effect of Fe₃O₄ on PLA (a) effect on T_g (b) effect on T_{cc} (cold crystallization temperature). Reproduced from Yu, B., Wang, M., Sun, H., et al., 2017. Preparation and properties of poly (lactic acid)/magnetic Fe₃O₄ composites and nonwovens. RSC Advances 7 (66), 41929–41935.

- (1) Shape memory polymer (SMP): these polymers are naturally smart. There is no need for reinforcement to make them respond or to memorize their shape while triggered by some external stimulus (Zhou and Sheiko, 2016).
- (2) Shape changing polymer (SCP): these polymers can change their shape based on some external actuation but cannot memorize the shape. They remain in changed shape till they are triggered with external stimulus but as the external stimulus is off they come back to their original shape (Zhou and Sheiko, 2016).
- (3) Meta-materials: this category of smart components is one of those specially designed components which show change in property due to inherent printed geometry by 3D printing (Ge et al., 2014).

Programming Techniques for Smart Behavior

1.3.1 One step programming

One step programming means a component is coded in a way that it can respond to only one stimulus particularly and can change its shape for one stage and to make it to its original shape one have to apply another stimulus as represented in Fig. 2(a) (Hager et al., 2015).

Two step programming

As in the case of one step programming there was a restriction that the material cannot regain its shape without external stimulus application but in two step coded material the composite can regain its shape with the same stimulus by making on and off to the stimulus as shown in Fig. 2(b) (Hager et al., 2015).

Fig. 3 Hysteresis loop of PLA with Fe_3O_4 . Reproduced from Yu, B., Wang, M., Sun, H., *et al.*, 2017. Preparation and properties of poly (lactic acid)/magnetic Fe_3O_4 composites and nonwovens. RSC Advances 7 (66), 41929–41935.

Fig. 4 (a). One step coding. (b). Two step coding. (c). Multy step coding of polymers.

Multy step coding of polymers

Coding of material for more than two stages with different or same stimulus is particularly known as multy step memory coding (Hager *et al.*, 2015). **Fig. 4(c)** shows the multy step coding of material.

Various Techniques and Smart Material Used for 3D Printing

Table 1 shows the diverse range of techniques applied for 3D printing for e.g., stereo lithography (SL), digital light processing (DLP), sacrificial mold technique (SMT), fused deposition modeling (FDM) and direct wire printing (DWP). Though DWP and SL is the most familiar techniques used in printing smart materials (Mu *et al.*, 2017; Cui *et al.*, 2016a,b; Borrello *et al.*, 2018; Nowicki *et al.*, 2016; Yang *et al.*, 2015; Mao *et al.*, 2016; Kutikov *et al.*, 2014; Singh *et al.*, 2019; Wu *et al.*, 2016).

Table 1 Different technology and materials for 3D printing

Technique	Material	Application
SL (stereo lithography)	Hydrogels such as Agarose and alginate, methacrylated hyaluronic acid and Soyabean oil epoxidized acrylate, etc.	Scaffolds for biomedical applications
Digital light processing (DLP)	Ethylene glycol phenyl ether acrylate (EGPEA), photo-curable methacrylate-based copolymer networks, photo-curable resin with multi-walled carbon nanotubes (MWCNTs), Polycaprolactone dimethacrylates	Tracheal stent for biomedical field
FDM (Fused deposition modeling)	PLA, poly (D, L-lactic acid-co-ethylene glycol-co-D, Hydroxyapatite, Polyurethane HA-PELA and L-lactic acid) (PELA) composites	Smart 4D filaments
DWP (Direct write printing)	Glassy shape memory polymer and Tangoblack1 and VeroWhite1 PLA, dichloromethane and benzophenone	Self-folding and expansion Self-folding and expansion
Sacrificial mold technique	PLA and Poly vinyl alcohol (PVA)	Self-folding and expansion

**Fig. 5** Structure of PLA with two roots.

Research Gaps

Based on literature review, gaps have been identified:

- Many researchers have explored the printing via FDM for commercially available materials, but very few have worked on thermo-sensitive and magneto-sensitive filament for 4D applications. In other words, the filament developed is sensitive for actuation with stimulus either heat, magnetic field or both. The 4D printing is upcoming field in AM and not much data has been reported regarding the 4-D printing with FDM (which is one of the low-cost AM techniques). Further it has been observed that very less has been reported on thermal and magnetic actuation together.
- PLA in combination of PVC reinforcement is very less studied which may be used as waste management of polymers as waste PVC can be reinforced into matrix of PLA.
- Smart materials are used in actuators, sensors applications and can be fabricated by conventional manufacturing processes as well as by 3D printing. Some of the commonly reported smart materials are PLA, magnetite powder. Still no work has been reported for preparing 4D printed parts by using PLA, PVC, Wood Dust and Magnetite powder with FDM process.

Proposed Material and Working Mechanism

PLA

PLA is a thermoplastic of semi crystalline nature in which crystalline structure as well as amorphous structure is present in some mixture. The glass transition temperature of PLA lies between the range of 58–60°C and melting temperature (T_m) varies between the range of 150–220°C (Martin and Avérous 2001; Jing *et al.*, 2014). PLA a biodegradable thermoplastic and bioactive thermoplastic is aliphatic polyester derived from resources which are renewable such as cassava roots, corn starch, and sugarcane in

Table 2 Mechanical properties of PLA

Properties	Values with respective units
Crystalline nature	Semi crystalline, 0%–37% Amorphous
Young modulus	1.2–3 GPa
Melting temperature	145–186°C
Glass transition temperature	50–64°C
Elongation at break	2%–6%
Tensile strength	28–50 MPa

**Fig. 6** PVC polymerization.

different parts of world. In 2010 PLA had the second largest consumption volume of any bio plastics of the world (see “Relevant Website section”). **Fig. 5** shows the basic structure of PLA which can be made through two available routes (Södergård and Stolt, 2010):

Using metal as catalysts with Ring opening polymerization of lactide

(1) Esterification

Table 2 shows the mechanical properties of poly lactic acid (PLA) (Mark, 1999) which are important from the research point of view.

PVC

Polyvinyl chloride (PVC) polymer which is a thermoplastic is the commonly available plastic polymer which have insulating as well as fire resisting property due to which it finds application in most of the electronic components such as cable, wires (Zabłocka-Malicka *et al.*, 2015; Yang *et al.*, 2007). Polyvinyl chloride is produced by polymerization of the vinyl chloride monomer (VCM) (Chanda and Roy, 2006), as shown by **Fig. 6**.

Wood Dust

Wood dust, which is of micro size is generated in the dealing of wood for different range of applications, is a complex substance. Composition of wood dust is totally dependent over the type of wood used for the particular application. Cellulose (approximately 40%–50%), is the main component of wood dust, other substances such as lignin, polyoses and a large and different number of molecules of low molecular mass which can alter the properties of wood. These low molecular mass components include non-polar organic extractives (waxes, resin acids, glycerides, terpenes, alcohols, steryl esters, sterols and fatty acids), polar organic extractives (quinones, lignans, flavonoids and tannins) and extractives which are water soluble (inorganic material, alkaloids, proteins and carbohydrates) (IARC, 1995).

Magnetite Powder (Fe₃O₄)

Study reveals that Iron oxide generally found in three composite structure such as FeO, Fe₂O₃ (hematite) and Fe₃O₄ (magnetite). The FeO exists as a rock salt structure and is having anti-ferromagnetic behavior at low temperature. Fe₂O₃ (hematite) is having corundum structure and anti-ferromagnetic behavior. Fe₃O₄ possess spinal-structure as well as holds ferromagnetic order a corundum structure and an essentially anti-ferromagnetic order (Shiroishi *et al.*, 2003).

Table 3 provides the different properties of different Iron oxides which are further considered for material selection for research purpose (Cornell and Schwertmann, 2003).

Table 3 Properties of different iron oxide

Property	Hematite	Magnetite	Maghemite
Molecular formula	Alpha-Fe ₂ O ₃	Fe ₃ O ₄	Gamma-Fe ₂ O ₃
Density (g/cm ³)	5.26	5.18	4.87
Hardness	6.5	5.5	5
Type of magnetism	Weakly ferromagnetic or anti-ferromagnetic	Ferromagnetic	Ferri-magnetic
Curie temperature (K)	956	850	820–986
Crystallographic system	Rhombohedral	Hexagonal Cubic	Cubic or tetrahedral
Structural type	Corundum	Inverse spinal	Defect spinal

**Fig. 7** Proposed methodology for in-house fabrication of 4D feedstock filament.**Twin-Screw Extrusion (TSE)**

Cletral, 20 year back pioneered the “Twin screw extrusion” process for continuous production of uniform and finely structure components. Feed stock filament for 3D FDM printers, processing of different type of bio-plastics, thermoplastics etc. are some of the uses of TSE. Blending of different proportions of composite and giving a good quality product with good process control of machine conditions is the primary benefit of TSE. Different parametric conditions can be used with

Table 4 Composition of mixture

Serial no.	Polymers and reinforcements	Weight in grams (g)	Percentage of granules in composite mixture (%)
1	PLA	20	50
	PVC	10	25
	Magnetite powder (Fe_3O_4) (44 μm)	8	20
	Wood dust (50 μm)	2	5
2	PLA	21	52.5
	PVC	6	15
	Magnetite powder (Fe_3O_4) (44 μm)	10	25
	Wood dust (50 μm)	3	7.5
3	PLA	20	50
	PVC	9	22.5
	Magnetite powder (Fe_3O_4) (44 μm)	7	17.5
	Wood dust (50 μm)	4	10

**Fig. 8** Feedstock filaments for three proportions.**Table 5** Magnetic property values for the three extruded filaments

Sl. no.	Magnetic properties	Composition		
		Composition 1	Composition 2	Composition 3
1	Magnetization (emu/cm^3)	0.184	0.228	0.154
2	Coercivity (H_c) (Oersted(Oe))	72.36	74.97	76.88
3	Retentivity (M_r) (Tesla (T) or Gauss (G))	8.88E – 03	1.12E – 02	7.93E – 03

machine depending on requirement of design of experiment's which is provided by machine such as wide range of temperature, torque, rotation, and variable size of component. The basic benefit of using TSE is its different blending in bulk that gives the precise product output. In TSE process, the raw materials could be granules, solid particles, and powder or mixture of any of them (Dombe *et al.*, 2015).

Methodology

Fig. 7 shows the methodology adopted for the present study which clearly shows stepwise method to prepare a 4D feedstock filament for FDM applications.

Magnetostrictive Polymer Composite 4D Feedstock Filament: A Case Study

4D feedstock filament preparation for 3D printing is a precursor to the present study. It is necessary to have a proper mixture ratio of polymers and reinforcement so that the prepared feedstock filament can be used in fused deposition

Fig. 9 Hysteresis loop for three filaments.

modeling (FDM). Therefore with repeated number of trials 3 composite mixture ratio is selected for better flowability (without choking of die), for precise size of obtained filament (diameter 1.7–1.75 mm) and for ease of extrusion with twin screw extrusion machine. **Table 4** shows all the selected composition with their percentage in the composite for the purpose of extrusion.

Fig. 8 shows the filaments for the three mixtures given in **Table 4** which shows that the given proportion is totally workable with twin screw extrusion machine and it was easy to obtain proper size of filaments with these taken mixture ratios.

For 4D properties, the obtained filaments also possess some magnetic property which is ensured by vibration sample magnetometer testing (VSM) which was performed by LAKESHORE model VSM machine having range of 1.5 tesla (T). The obtained value of magnetization (emu/volume), retentivity (tesla (T)) and coercivity (Oersted (Oe)) are given in **Table 5**.

Fig. 9 shows the hysteresis loop of the three filaments obtained by twin screw extrusion which clearly shows that there is some magnetic property in the filaments which necessary for 4D application such as self assembly.

Summary

In this article, a frame work for preparing in-house 4D feedstock filament with 3D printing has been proposed. This route will lead to development of customized 4D feedstock's filament for 4D properties that will ultimately lead to some attractive attributes such as:

- The preparation of various proportions of magnetite powder, PLA, PVC and wood dust for 4D applications and preparation of FDM feed stock filament (for commercial open source 3D printer) of magnetite powder, wood-dust, PLA and PVC by mixing with TSE.
- Establishing rheological (melt flow index), thermal properties for the filaments prepared by TSE and preparation of thermal actuation analysis data followed by parametric optimization of feedstock filament wire based upon metallurgical testing and mechanical (tensile test, scanning electron microscope) and selection of best feed stock filament For 4D capabilities.
- Parametric optimization of filament wire based upon vibration sample magnetometer (VSM) and selection of best wire filament condition needs to be performed. Finally printing of functional prototypes using FDM with best feedstock filaments and optimized data for best setting conditions based upon XRD, FTIR DMA data for best setting wire filaments and for printed components.

Acknowledgment

The author is highly obliged to GNDEC manufacturing lab and TIET providing labs to perform the current investigation.

Introduction

Additive manufacturing (AM) is a promising technology for the generation of customized products and prototypes requiring geometrical complexity. Often interchangeably labeled as 3D printing; ISO/ASTM standards define 3D printing as the process of fusing or depositing materials such as polymers, metals, ceramics, and living cells, layer by layer to produce an architecture dictated from a digital CAD software file (Gibson *et al.*, 2014). AM has been utilized within many fields, one of which is the medical device industry, with the use of 3D printing in this field expanding rapidly to improve health care. In 2018, the 3D-printed medical devices market which is segmented into equipment (3D printers), materials and software & services; accounted for a value of US\$ 0.84 billion in 2017, and is projected to grow to US\$ 1.88 billion by 2022 at a Compound annual growth rate (CAGR) of 17.5% (Markets and Markets™, 2017). Other reports state that the global 3D printing healthcare market size, categorized as components, technologies and applications; in total was valued at US\$ 973 million in 2018, and is projected to reach US\$3.7 billion by 2026 growing at a CAGR of 18.2% from 2019 to 2026 (Allied Market Research, 2019). Europe will likely continue as a major stakeholder in the widespread fabrication of 3D-printed biomedical devices, indicated by market research that predicts Europe will double production by 2025–2029 (Future Market Insights, 2019).

The versatility and the opportunities 3D printing presents is being increasingly appreciated. With the 2019–2020 coronavirus pandemic; engineers and designers quickly turned to 3D printing to rapidly replenish a shortage of respiratory valves; whereby volunteers reverse engineered a patented valve to produce 100 3D-printed valves in 24 h at a cost of approximately US\$ 1 per unit (Healthcare IT News, 2020). In the same fashion, the i-Form research facility based in University College Dublin (UCD) Ireland, designed and manufactured face shields for frontline medical staff working with Covid-19 patients to hospitals in Dublin and to Health Service Executive (HSE) coronavirus testing centers around the greater Dublin area (The Irish Times, 2020). Moreover, to develop measures against the coronavirus crisis, a Belgium-based pioneer in 3D printing has created a non-invasive Positive End Expiratory Pressure (PEEP) mask Connector; a device to convert standard equipment available in most hospitals, into a mask to facilitate breathing for patients by creating positive pressure in the lungs (Materialise, 2020).

3D printing for biomedical applications can be categorized into engineered tissue and biofabrication (Zadpoor and Malda, 2017), surgical implants (Willemsen *et al.*, 2019), and drug delivery (Norman *et al.*, 2017). Tissue engineering merges the principles of materials and cell transplantation to develop substitute tissues and/or promote endogenous regeneration based on key engineering principles and typically utilizes biomaterial scaffolds as platforms to promote such regeneration and/or delivery therapeutic cells or biochemical factors to do so. Instinctively, tissue engineering has begun to employ 3D printing technology to fabricate such scaffolds and, in some cases, simultaneously print scaffolds, cells and biochemical factors together which can provide more scalable and reproducible medical solutions. With their development progressing at a rapidly growing rate, patient-specific 3D printed cell-laden products could positively influence the patient recovery time and therapeutic outcome (Mertz, 2013).

Furthermore, the pharmaceutical industry has adopted AM towards achieving more personalized medicine. AM technology allows printing specific doses on demand, with reduced cost, ease of use and desired drug release kinetics to improve patient care (Musarrat *et al.*, 2018). The ability to predesign geometries with desired release profiles and quantities by amending the CAD file is breaking new ground in the application of 3D printing for drug product development (Azad *et al.*, 2020).

From a materials point of view, currently approved AM technologies can be organized into seven categories; that of vat photopolymerization, powder-based, materials jetting, binder jet printing, materials extrusion, direct energy deposition and

Fig. 1 Brief graphical abstract of common AM methods. The checkmarks apply to the technologies that (to the best of our knowledge) have been used for biomedical applications.

laminated object manufacturing (Lim *et al.*, 2018; Yang *et al.*, 2018a). These categories can be further expanded into the general available 3D printing technologies and are summarized in Fig. 1.

Photo-polymerization processes rely on selectively curing a liquid photopolymer under a radiation source of appropriate wavelength (Yang *et al.*, 2001). Powder bed fusion (PBF) is a subset of AM using a numerically controlled heat source, building a component layer-by-layer from a pre-placed powder (Goodridge and Ziegelmeier, 2017). Materials jetting process involves spraying a layer of photopolymer from hundreds of tiny nozzles while simultaneously curing the layer with UV light before printing the next layer (Kelly *et al.*, 2018). This technique is a useful choice for realistic prototypes, providing high resolution, accuracy and a smooth surface finish (Biglino *et al.*, 2013). Binder jetting is an alternative printing method placing powder layer by layer joining at the selective areas with a liquid binder. Laminated object manufacturing is an approach to create a part by lamination of sheet feedstock, which is laser-cut along contours instructed by an STL file-generated tool path (Safari *et al.*, 2001). In directed energy deposition technology, an electron or laser beam is used to melt and solidify the starting material which is supplied as a powder, filament or wire in a layer-wise pattern (Bose *et al.*, 2018).

Material extrusion 3D printing technology is perhaps one of the most popular AM methods for scaffold fabrication as it offers a wide range of printable biomaterials in terms of design and geometry and inexpensive equipment (Derakhshanfar *et al.*, 2018). Extrusion rapid prototyping methods can be categorized as fused filament fabrication (FFF) or its trademarked term fused deposition modeling (FDM™), melt-electrospinning writing, known as melt-electro writing (MEW), and extrusion-based

bioprinting (EBB). In this article, we will present the fundamentals of FDM, MEW and EBB and discuss biomaterial scaffolds and their application in tissue engineering and medical technologies. We also discuss emerging prospects in these fields to overcome current challenges and realize the next generation of 3D printing processes.

Fused Deposition Modeling (FDM™)

In 1992, Scott Crump secured a U.S. patent for an "apparatus and method for creating three-dimensional objects" (Crump, 1992). He termed the technology Fused Deposition Modeling (FDM). FDM concerns a thermoplastic filament extruded from a hot nozzle deposited as a semi-molten polymer in a layer by layer process (Zein *et al.*, 2002). This technique has generated an increased demand in rapid prototyping due to its simplicity, low cost, table-top sized equipment and low-risk processes which avoid the use environmentally hazardous solvents (Garzon-Hernandez *et al.*, 2020).

FDM can yield 3D structures with fully interconnected channel networks, and highly controllable porosity (Zein *et al.*, 2002). The stiffness, yield strength, flexural strength and therefore the quality of the 3D parts are influenced by the internal structure, pore sizes and shapes of the deposited materials (Dhinakaran *et al.*, 2020). Nowadays, various types of biomaterials are used with FDM, including pure polymers, copolymers, polymer blends and composites.

3D printed tissue engineered scaffolds can often be designed with complex configurations and highly interconnected pore structures to provide a suitable pore structure for cell attachment and proliferation, while retaining the required mechanical function (Hutmacher, 2001). Porous scaffolds with sufficient surface areas are often produced using traditional methods such as freeze drying, solvent casting, fiber meshes/fiber bonding, phase separation, and gas foaming. However, achieving customized scaffolds which are geometrically compatible with a patient's local anatomy with specific spatial patterning is one advantage of AM (Jariwala *et al.*, 2015).

For instance, much effort has focused on the fabrication of 3D fibrous structures for bone tissue engineering to produce mechanically competent implants that also provide a base for cell attachment and proliferation (Bendtsen *et al.*, 2017; Nyberg *et al.*, 2016). Cancellous bone is spongy in nature with a porosity ranging from 50 to 90 vol% (Bose *et al.*, 2013), in contrast to cortical or compact bone (which contributes more to the mechanical role of bone) having less than 10 vol% porosity (Fuchs *et al.*, 2019). Bone porosity can change with age, disease states and lifestyle (Fuchs *et al.*, 2019). On the basis of Magnetic Resonance Imaging (MRI) and micro computed tomography (μ -CT), the anatomic geometry of bones and/or their defects can be obtained and imported as a patient CAD model for scaffold fabrication at a microstructural level (Tavares and Natal, 2018). Porous structures have been designed and manufactured using FDM to achieve predefined porosity levels and pore sizes in order to promote osseointegration (Buj-Corral *et al.*, 2018). CT-guided FDM has also been reported in the fabrication of PCL/HA 3D bone scaffolds with both cortical and cancellous bone regions (Xu *et al.*, 2014). These reports demonstrated an appropriate in vivo biocompatibility, new bone formation and a predictive biodegradation rate which holds promise for future bone regenerative applications (Xu *et al.*, 2014). In another piece of work, the grafting of FDM-printed PEEK reinforced with carbon fiber was successfully fabricated yielding significant mechanical properties to be employed as the orthopedic and dental implant materials (Han *et al.*, 2019).

With regard to the 3D printing of drug loaded structures, antibiotic- and chemotherapeutic agents have been incorporated into PLA filaments which maintained mechanical integrity throughout the FDM process (Weisman *et al.*, 2015). This can offer patient-specific scaffold containing antibiotic treatment and/or drug delivery with a sustained-release capacity. Other reports have presented FDM fabricated polycaprolactone-tricalcium phosphate (PCL-TCP) meshes for the delivery of gentamicin sulfate (GS) to achieve an effective localized release when applied as a wound dressing, eliminating bacteria while still possessing appropriate biocompatibility with dermal fibroblasts (Teo *et al.*, 2011). Moreover, in vivo investigations have demonstrated that this platform (in particular PCL-15 wt% GS) operated as a highly effective local antibiotic delivery vehicle capable of eliminating bacterial infections within 7 days (Teo *et al.*, 2011). PCL filaments loaded with quinine produced by hot melt extrusion have also demonstrated tailored release profiles using this model drug in a proof-of-concept study (Kempin *et al.*, 2017). These studies demonstrate the capacity of FDM to produce customized implants with controlled drug delivery.

Despite the clear benefits of FDM, some limitations are present. These include filament temperature control which affects the viscosity of melted polymer, as well as the fabrication of functional interconnected network structures with an adequate surface area-to-volume ratio. Moreover, when 3D-printed materials require nano and micro reinforcement using ceramics, polymers or metal nanoparticles (Walmsley *et al.*, 2015), the porosity of FDM printed constructs can be even lower because a larger filament diameter is required to prevent clogging during the extrusion (Grottkau *et al.*, 2020). For instance, FDM fabrication of HA reinforced PLA scaffolds designed towards small bone defect replacement have been reported with a porosity of only 30% (Senatov *et al.*, 2016).

Melt Electro-Writing (MEW)

Recently, melt electrospinning technology has emerged as an approach to fabricate ultrafine fibers from polymer-based inks. MEW, as an electrohydrodynamic approach; deposits ultrathin fibers layer-by-layer on a stage (Farrugia *et al.*, 2013) or a mandrel (Jungst *et al.*, 2015) collector dictated by G-code commands to fabricate 3D textiles and scaffolds for tissue engineering (Dalton *et al.*, 2013). A melt electrospinning printer typically contains a static syringe heater which melts material and an applied air pressure forces polymer to

flow out through a spinneret which is linked to a high voltage source (Wunner *et al.*, 2017). A threshold voltage charges the polymer structure to generate a steady cone-jet structure. A high viscosity polymer with low conductivity results in a stable Taylor cone and straight melt flow to precisely deposit the continuous fiber (Farrugia *et al.*, 2013). Linear writing is possible when the collector speed is higher than critical translation speed in order to avoid oscillatory deposition of the fiber (Hochleitner *et al.*, 2016).

Fiber diameter and morphology can have a significant influence on cell behavior and mechanical performance of materials (Cardwell *et al.*, 2014). Therefore it is important to note that MEW, can achieve fiber diameters less than one micron; much smaller when compared to FDM which achieves on average a minimum diameter of 200 μm (Lam and Chen, 2019). Moreover, well-aligned MEW fibers at sub-micron diameter offer the benefit of desired structure in nano-level with reported fiber diameter of 292 nm produced from single collector and 270 nm for dual collector systems (Dalton *et al.*, 2007; Dalton *et al.*, 2006).

While 3D printing of polymer scaffolds is typically applied to hard tissues, MEW allows for the manufacture of small diameter ($> 20 \mu\text{m}$) fiber structures suitable for soft-tissue engineering (Robinson *et al.*, 2019), such as cartilage (Visser *et al.*, 2015), periosteum (Baldwin *et al.*, 2017), nerves (Petcu *et al.*, 2018), skin (Farrugia *et al.*, 2013), and cardiac tissue (Bas *et al.*, 2018). Producing such small diameter fibers enables the fabrication of engineered fibrous architectures similar to the native ECM (Eichholz and Hoey, 2018). MEW has been used to fabricate skin substitutes consisting of PCL scaffolds with 7.5 μm diameter fibers with interfiber distances of approximately 46 μm , facilitating fibroblasts to attach to and infiltrate through the melt-electrospun scaffolds both laterally and vertically to form a 3D cellularized construct (Farrugia *et al.*, 2013). MEW has also been used to produce tubular scaffolds whereby PCL tubes were fabricated by MEW depositing 20 μm diameter fibers at different winding angles and collecting on rotating cylinder (Brown *et al.*, 2012). These tubular scaffolds acted as provisional substitutes for ECM and demonstrate human osteoblast, mouse osteoblast and human mesothelial cell compatibility (Brown *et al.*, 2012).

MEW has also been used to create sacrificial PCL templates to achieve a hierarchical porous structure of poly(2-oxazoline) hydrogels (Haigh *et al.*, 2016). Such indirect printing of pore structures within hydrogels can provide highly defined hierarchical structures to control diffusion of nutrients, growth factors or pharmaceuticals.

Extensive z-direction mobility is avoided in the electrospinning field to avoid an excess charge becoming trapped within the deposited polymer in the region close the spinneret (Wunner *et al.*, 2018), which limits the height of scaffolds that can be produced using this technique. In an innovative approach to overcome this obstacle, a mechatronic system was designed to control the collector distance in a MEW set-up (Wunner *et al.*, 2018). This has enabled significantly thicker scaffolds (exceeding 7 mm) to be fabricated.

Hydrogels (alginate and methacrylated gelatin) reinforced with a highly organized porous network of PCL fabricated by MEW enabled the engineering of composites with similar compressive mechanical properties to that of native articular cartilage, without negatively impacting the capacity of the construct to support the deposition of a cartilage-like tissue by encapsulated cells (Visser *et al.*, 2015). Similar approaches have been used to reinforce PEG/heparin hydrogels (Bas *et al.*, 2017). In a cardiac application, melt-electrowritten constructs of a hydroxyl functionalized polyester have been designed to mimic the mechanical properties of the native myocardial tissue, whilst simultaneously promoting cardiac progenitor cell (CPC) alignment (Castilho *et al.*, 2017).

The main advantage of MEW is achieving highly precise constructs from ultrafine filaments which can be used to obtain complex designs for different applications in tissue engineering. One main drawback of MEW is the hydrophobic nature of the polymers commonly used in MEW due to their hydrocarbon backbones which prohibit cell adhesion and appropriate biocompatibility (Richbourg *et al.*, 2019; Shin *et al.*, 2003). Contingency for this is often post processing surface treatment of the relatively hydrophobic melt electrowritten fibers by plasma, NaOH treatment, or coating using a secondary polymer (Afghah *et al.*, 2019).

As demonstrated in Fig. 2, FDM scaffolds can have orderly and controlled geometries together with a low porosity which offers high level of biocompatibility (Li *et al.*, 2019), while multimodal MEW scaffolds possess highly-tunable geometry and superior level of porosity (Hrynevich *et al.*, 2018) (Fig. 3). Taken together, melt electro-writing provides fibrous scaffolds with smaller fiber diameters (and therefore higher overall porosity achievable) and designs at a higher resolution which is favorable for cell invasion and growth.

Extrusion-Based Bioprinting (EBB)

3D Bioprinting is concerned with a layer-by-layer, precise positioning of living cells, biomaterials, and active biomolecules to construct 3D structures (Murphy and Atala, 2014); with a focus on three approaches: biomimicry, autonomous self-assembly and mini-tissue building blocks (Murphy and Atala, 2014). Its most common form; extrusion-based bioprinting; is the extrusion of cell-laden hydrogels or 'bio-inks' onto printing stages, in a layer-by-layer fashion to form 3D platforms of various sizes, shapes and resolutions.

A major advantage of this process is the ability to print high cell densities at a high production (Rider *et al.*, 2018). However, its relatively low resolution in comparison with conventional 3D printing methods is a limitation of this method (Duan *et al.*, 2013).

Extrusion based bioprinting systems typically employ materials (hydrogel bioinks) with high viscosity, predetermined by the polymer concentration and molecular weight (e.g., viscosity of Lutrol® F 127 with 12 kDa molecular weight $\sim 600 \text{ kPa s}$). Therefore, 3D printing hydrogels often results in reduced accuracy and resolution (typically $> 100 \mu\text{m}$), and the final shape of 3D constructs often relies on crosslinking post-printing. Extrusion resolution can be enhanced by utilizing a smaller nozzle, though this comes at the cost of cell damage due to an increased shear force during printing (Chang *et al.*, 2008). Moreover, selecting the correct material is a must to achieve complex anatomical architectures with an appropriate degree of stiffness to preserve viability of embedded cells (Murphy and Atala, 2014).

One target for EBB based bioprinting is skin, which being the largest organ in the human body, provides protection from the external environment, regulates body temperature, and preserves body fluid. Extensive injuries, i.e., deep skin burns and chronic wounds, and

Fig. 2 Digital photograph, SEM, confocal laser scanning microscopy and Live/dead analysis of bone marrow-derived mesenchymal stem cells (BMSCs) cultured on PCL structures fabricated by FDM. Adapted from Li, J., Li, L., Zhou, J., *et al.*, 2019. 3D printed dual-functional biomaterial with self-assembly micro-nano surface and enriched nano argentine for antibacterial and bone regeneration. *Applied Materials Today* 17, 206–215.

Fig. 3 Example of 3D printed PCL scaffold using MEW. Melt electrospun mesh of PCL starting with large diameter fibers (40 μm) at the bottom, down in diameter to 4 μm at the highest point. Included two 7.5 μm diameter “catching fibers” between the two large diameter fibers. (A) Schematic of tapered scaffold, (B)–(D) SEM micrographs from both sides of scaffolds, (E) 3D spheroids generated from 5000 human adipose-derived stem cells (hASCs) each in agarose-coated 96-well plates, (F) Cell viability in fluorescence microscopic image. At the culture of hASC spheroids, catching fibers inhibit spheroids from falling through the scaffold. Adapted from Hrynevich, A., Elçi, B.Ş., Haigh, J.N., *et al.*, 2018. Dimension-based design of melt electrospun scaffolds. *Small* 14 (22), 1800232.

full-thickness skin wounds, can be difficult to repair. Bioengineered skin scaffolds can be fabricated from both natural and synthetic materials and cellularized in vitro. Most recently, a patient-specific 3D printed mask for facial skin reconstruction; an engineered skin substitute combining a wound dressing layer that fits onto the facial wounds has been reported (Seol *et al.*, 2018). The product printed, *BioMask* (not to be confused with the trademarked antimicrobial face mask of the same name); consisted of three layers; a porous polyurethane (PU) layer, a keratinocyte-laden hydrogel layer, and a fibroblast-laden hydrogel layer improved regeneration of skin tissue, consisting of epidermis and dermis layers, on the complex facial wounds in a mouse model (Seol *et al.*, 2018).

The printability of 3D structures containing cells and ECM components has progressed to simplified biological tissues, however, bioprinting of functional organs remains a challenge (Daly *et al.*, 2016b). An alternative approach to directly bioprinting complex solid organs is to bioprint their less complex developmental precursors using tissue-specific stem cells. Multiple-tool biofabrication (reinforcement of stem cell laden hydrogel constructs by parallel deposition of a thermoplastic polymer fiber) has been used to engineer anatomically accurate, hypertrophic cartilage templates with the capacity to mature over time in vivo into vascularized bone organs (Daly *et al.*, 2016b). These bioprinted precursors matched the overall shape of the bone organ (Daly *et al.*, 2016b), potentially enabling their use for complex clinical applications.

A major challenge for manufacturing functional tissue is the ability to replicate highly vascularized tissues containing entangled networks of blood vessels such the pulmonary, liver, and urinary systems possessing hollow and tubular structures. Extrudable liver-specific bioinks of HA and gelatin-based hydrogels with primary liver spheroids have been used to construct in vitro liver structures with suitable stiffnesses and high cell viability (Skardal *et al.*, 2015). iPSC-derived hepatic spheroids within alginate/Pluronic F-127 bioinks together with iPSC-derived non-parenchymal cells, have also been developed as autologous liver grafts (Goulart *et al.*, 2019). Hydrogels combined with patient derived cells have been used to print thick and vascularized cardiac patches designed to match the anatomical structure of the left ventricle (Noor *et al.*, 2019). Moreover, this same study demonstrated printability of volumetric structure of small-scale cellularized human heart (height: 20 mm; diameter: 14 mm) within the support medium of two discrete bioinks, containing Cy5-prestained CMs or RFP-expressing ECs (Noor *et al.*, 2019).

Polymer-Based Biomaterials for Extrusion Techniques

The ultimate aim of 3D biofabrication approaches is to engineer biocompatible tissue structures with precise architectures and mechanical strength. A key influence on this aim is the selection of the materials to form the desired shape. Therefore, the chemical, rheological, mechanical and biological properties of the printable bioink must be considered. Extrusion printers are employed to process the bioink which themselves are affected by mechanical forces and shear stresses during the deposition from the nozzle. Bioinks with viscoelastic behavior, such as shear thinning characteristics, are promising candidates to compensate for this high shear stress associated due to their high viscosity (Guvendiren, 2019). The extrusion process typically uses a pneumatic actuator or screw device to feed natural or synthetic material through a nozzle or needle to lay in layer-by-layer fashion and forms a digital 3D object (Placone and Engler, 2018). Scaffolds with complex geometries require carefully chosen materials which match the printing conditions for specific applications. The major criteria include biodegradability, pore interconnectivity, pore size, porosity, mechanical and physical properties that are essential for the target tissue that needs to be engineered such as bone, cartilage, blood vessel, or skin.

Some of the popular biopolymers for the extrusion methods are Acrylonitrile Butadiene Styrene (ABS), Polycarbonates (PC), Polyphenylsulfone (PPSU), nylon, Polyether ether ketone (PEEK), Polyetherimide (PEI: also known as ULTEM), thermoplastic Polyurethane (PU), aliphatic polyesters such as PCL, PLA and poly glycolic acid (PGA) and natural/synthetic hydrogels (Dhinakaran *et al.*, 2020; Gregor *et al.*, 2017; Zhao *et al.*, 2018).

Thermoplastic Materials

Biodegradable polymeric materials in both natural and synthetic categories are favored to promote the organization, growth, and differentiation of cells in 3D structures (Gregor *et al.*, 2017). PCL is often used in Food and Drug Administration (FDA) approved devices and implants, and possessing a low melting point ($\sim 60^{\circ}\text{C}$) and a compressive modulus in the range of 300 MPa (Eshraghi and Das, 2010); is commonly used to produce scaffolds for both load bearing and non-load bearing applications (Siddiqui *et al.*, 2018). Polymer blends with bio-ceramics such as hydroxyapatite (HA), beta-tricalcium phosphate (β -TCP) and biphasic calcium phosphate (BCP) offer osteoinductive and osteoconductive properties (Huang *et al.*, 2018). PLA is a biodegradable polymer commonly used for orthopedic and dental applications, for example as screws, pins and arrows in surgeries including the items of the mandibular joint, facelifts, bone fragments, meniscus repair, hyaline cartilage fixation, and ligament reconstructions (Narayanan *et al.*, 2016). FDM fabricated PCL-HA porous scaffolds can meet the bone repair requirements in terms of mechanical strength, providing a potential alternative to autografts and allograft for bone regeneration (Yao *et al.*, 2015).

To date, PCL (Brown *et al.*, 2016), Poly(propylene) (PP) (Nayak *et al.*, 2012), Poly(2-ethyl-2-oxazoline) (POZ) (Hochleitner *et al.*, 2014), Poly-Hydroxymethyl glycolide-*co*- ϵ -caprolactone (pHMGCL) (Castilho *et al.*, 2017), PEG-block-PCL (Dalton *et al.*, 2008), PLGA (Kim *et al.*, 2010), PLA (Zhou *et al.*, 2006), PMMA (Wang and Huang, 2009), poly(urea-siloxane) (Hochleitner *et al.*, 2018) and poly(L-lactide-*co*- ϵ -caprolactone-*co*-acryloyl carbonate) (Chen *et al.*, 2016) have been reported to be printable with MEW.

Melt-electrowritten constructs of pHMGCL with a rectangular pattern yielded a directional mechanical anisotropy in scaffolds enabling alignment of cardiac progenitor preferentially along the dominating direction of the scaffold fibers (Castilho *et al.*, 2017).

Other reported designs detail development of a cell-free electroconductive melt-electrowritten PCL patch with an auxetic missing-rib design which conforms to the mechanics of human myocardium (Olvera *et al.*, 2020). This same study described functionalization using polypyrrole to yield conductivity in the range of 2–2.5 S m⁻¹ and cytocompatibility with human mesenchymal stromal cells.

Despite the ease of processing and biocompatibility of many thermoplastic polymers, a significant drop in elastic modulus can occur due to plasticizing effect of absorbed water (Surrao *et al.*, 2012) and elongation caused by creep (Chen *et al.*, 2014) in environments where materials are subjected to dynamic loading (Chen *et al.*, 2016). It is believed that crosslinking of polymer chains not only improves the stiffness and creep resistance, but also reduces this plasticizing effect (Landel and Nielsen, 1993).

As a result, using a cross-linkable polymer during MEW can facilitate a high modulus upon hydration (Chen *et al.*, 2016). This has led to reports of photo-cross-linked fiber scaffolds synthesized from ϵ -caprolactone (ϵ -CL), L-lactide (LLA), and a trimethylene carbonate-based monomer carry an acryloyl pendant group (5-methyl-2-oxo-1,3-dioxan-5-yl acrylate, or acryloyl carbonate (AC)), used to achieve an average modulus of 26 MPa in post-hydration conditions (Chen *et al.*, 2014).

Hydrogels

Extrusion-based technologies can utilize a wide range of materials presented in the liquid state (or materials that sufficiently shear thin during extrusion) that can then quickly solidify (Gibson *et al.*, 2014). Hydrogels with 3D viscoelastic polymeric structures display physical properties comparable with natural tissue which can be harnessed to match the final application in regenerative medicine (Lee and Kim, 2018). These materials are particularly suitable for use as bioinks harboring cells during the printing process; however there exists a defined range of opportunity, often termed the 'biofabrication window'; a concept that dictates the compromises between the printability of a bioink formulation and maintaining appropriate cell viability (Levato *et al.*, 2020). Printability will be dictated by bioink rheological properties and stiffness which will have a direct influence on shear stress, mechanosensing and nutrient perfusion experienced by embedded cells. Naturally derived hydrogels can be categorized in three groups as protein-based, polysaccharide-based and those derived from decellularized tissue (Catoira *et al.*, 2019). Collagen, elastin, fibrin, gelatin as protein-based natural hydrogels and polysaccharide-based materials such as agarose, alginate and chitosan (Catoira *et al.*, 2019) are precursors which can be extruded in a jelly-like form and then crosslinked with UV, ion or temperature-assisted during the post processing step (Wang *et al.*, 2020). A limitation of hydrogels is poor mechanical properties leading to eliminate their application in high load bearing situations (Daly *et al.*, 2016a). Therefore, constructs aiming to withstand such situations require reinforcement non-hydrogel inks.

Natural protein hydrogel bioinks

Collagen as the main insoluble fibrous protein in the body has long been used in tissue engineered scaffolds (Catoira *et al.*, 2019). 3D bioprinted constructs of collagen type I (COL) with sodium alginate (SA) and chondrocytes have been reported to possess favorable mechanical strength and biological functionality (Yang *et al.*, 2018b). In other work, a highly porous construct of cell-laden collagen/polyphenol was fabricated using a 3D cell printing system (Yeo and Kim, 2017). This hybrid structure, consisting of core-shell struts laden with hASCs and single struts with preosteoblasts (MC3T3-E1), exhibited improved cellular viability when compared to a standard alginate control ink (Yeo and Kim, 2017). Fibrin, a protein found in circulating blood; has been adapted to hydrogels that support stem cell culture and differentiation (Abelseth *et al.*, 2019). One biofabrication approach in the tissue engineering of a urethra has explored the construction of porous PCL/PLCL scaffolds within fibrin hydrogels. The resultant spiral scaffold contained multiple layers harboring urothelial cells and smooth muscle cells and possessed mechanical properties equal to the native urethra in rabbits (Zhang *et al.*, 2017). The high level of porosity in the scaffold facilitated cell-cell interaction between cell layers and a uniform nutrient transport inside the scaffold (Zhang *et al.*, 2017).

Polysaccharide-based hydrogel bioinks

Hyaluronic acid (HA) is a polysaccharide-based material and a major component of the extracellular matrix extensively found in vitreous and synovial fluids (Yoo *et al.*, 2005). HA has a slow gelation rate with low mechanical properties which is a major barrier to its use for scaffold generation (Noh, 2018). However, HA can be combined with natural/synthetic polymers to modify and meet the mechanical requirements for different applications such as cartilage tissue. A tailor-made methacrylated hyaluronic acid (MeHA) gel has been reported for the development of 3D printable scaffolds supporting bone-like tissue formation showing high levels of cell survival and spontaneous osteogenic differentiation in vitro (Poldervaart *et al.*, 2017).

Agarose is a thermo reversible polymer, suitable for diverse applications because of its reliable and robust gel forming properties (Xiong *et al.*, 2005). Hydrogel blends of agarose have been shown to yield stable 3D constructs and support endothelial and fibroblast cell growth (Kreimendahl *et al.*, 2017). Alginate as a biopolymer are negatively charged polysaccharides, can entrap water and other molecules via capillary forces and allow diffusion from inside out. This distinctive property makes it an attractive candidate for 3D printing bioinks (Gopinathan and Noh, 2018b). High strength 3D structures of cell-laden alginate-based hydrogel have been fabricated with fusion of adjacent hollow filaments (Gao *et al.*, 2015). The hollow alginate filaments support the mechanical integrity of the 3D bioprinting structure and work as built-in microchannels to deliver nutrients for cell growth (Gao *et al.*, 2015). In another study, a printability window for different molecular weights of alginate by varying the ratio of alginate to ionic crosslinker has been described and used to spatially define microenvironments and cellular phenotypes found in solid organs like a long bone using 3D bioprinting (Freeman and Kelly, 2017).

Synthetic and interpenetrating network hydrogel bioinks

Synthetic hydrogels possess the benefits such as precise control, reproducibility and desired mechanical properties with low toxicity which make them suitable candidates for cell-laden and drug carrying inks (Zhao *et al.*, 2018). Classic synthetic polymers employed in tissue engineering hydrogel scaffolds are synthetic PEG, Polyvinyl alcohol (PVA), Polyacrylamide (PAM) and Pluronic (Gopinathan and Noh, 2018b; Meng *et al.*, 2020). The most commonly used PEG-based bioinks in extrusion-based technique (Cui *et al.*, 2012; Wüst *et al.*, 2015) are PEGDA and poly(ethylene glycol) methacrylate (PEGMA) to improve the mechanical properties of 3D constructs. On-board photo-crosslinking systems have been used to enable 3D extrusion and curing of PEGDA hydrogels to achieve complex aortic valve geometries (Hockaday *et al.*, 2012). This work demonstrates that hydrogel extrusion is able to fabricate anatomical heterogeneous valve conduits which support cell engraftment (Hockaday *et al.*, 2012). PVA-based composite hydrogels proposed as part of an artificial cartilage replacement with a biomimetic gradient structure prepared via micro extrusion technology exhibited attractive bio-mechanical and bio-friction properties (Meng *et al.*, 2020).

Synthetic hydrogels with controlled mechanical and chemical properties, such as gelatin methacryloyl (GelMA) and PEGDA have been used as bioinks and cross-linked via click chemistry (Gopinathan and Noh, 2018a), ionic or physical bonding, thermo gelation, enzyme-enabled crosslinking and photopolymerization (Li *et al.*, 2018).

HA, hydroxyethyl acrylate (HEA) and gelatin-methacryloyl (HA-g-pHEA-gelatin) hydrogel based bioinks have demonstrated stable rheological properties and biocompatibility when printed in lattice forms (Noh *et al.*, 2019). A double network hydrogel with superior shear-thinning and recovery properties of gellan gum (GG) and fast UV cross-linking capability of PEGDA has been reported used as an encapsulating bioink for BMSCs and mouse osteoblastic cells encapsulated to create constructs modeling the ear and nose with high fidelity. This platform demonstrated biocompatibility and promise for the fabrication of living tissues at a human scale (Wu *et al.*, 2018).

Present approaches of the extrusion-based bioprinting have obtained significant advances but require considerable improvement. For instance, microstructure and anisotropy control in cell-seeded structures at a low cost while ensuring high quality is still a challenge in 3D printing. A move to 3D-bioprinting of collagen via freeform reversible embedding of suspended hydrogels (FRESH) to engineer functional organs has emerged in recent times (Lee *et al.*, 2019). FRESH operates by extruding a liquid from a syringe into a slurry, where the extruded material self-assembles into a solid filament (Hinton *et al.*, 2015). Recently, FRESH-printing of a left ventricle cardiac model using human stem cell-derived cardiomyocytes has been reported whereby a dual-material printing of a structural collagen bioink in combination with a high density cell bioink (Lee *et al.*, 2019). A neonatal scale human heart was fabricated using collagen which detailed the internal structure via printing of a cross-sectional view of (Lee *et al.*, 2019).

Conclusion

In summary, AM innovations in material design and fabrication processes could open up new developments in healthcare. The ability to use different 3D printing approaches with a large variety of polymers and their blends is still an emerging field. To achieve the optimal bioink, vascularization, compatibility and cell proliferation are fundamental factors to support tissue function in porous structures. Thus far, the field of additive manufacturing, specifically 3D printing in healthcare seeks to develop ideal polymeric materials to print engineering tissue constructions for mimicking biological entities and stimulating cell response which cause tissue regeneration and repair.

This article demonstrates the potential of extrusion-based technique for engineering personalized tissues and recapitulating patient-specific biochemical and biophysical microenvironments. However, despite recent improvements in design, inspired structures, and bioactivity of new polymeric materials to mimic native tissue, future research must address current limitations such as resolution, scalability, and the repertoire of materials available for these processes.

Introduction

The challenging technologies of the modern world demand the development of new materials that exhibit tailor-made nature, extensive functional and mechanical properties. In accordance with which the polymer matrix composite acquires a special place in the realm of new material development and technology related to it. The polymer matrix composite attributes that structure where the matrix phase and the reinforcing phase forms a thermodynamically stable interface and express the differential nature in terms of mechanical, rheological, and morphological properties. In addition to that, both of the phases should not be soluble to each other and always express the distinctive phases at the microstructural level. Fig. 1 expresses the fundamental criteria for defining any composite as a multifunctional composite.

The multifunctional polymer composite can be defined by understanding the four fundamental points. Both of the matrix and reinforcement should pose the distinctive characteristic in the microstructure. The matrix allows the formation of the interphase by sharing the common space around the reinforcing units. Because of this, the polymer matrix holds the reinforcement and retain the ability of the composite to sustain a higher amount of stress without showing any deformation. The absence of the distinctive phase or interface in the multifunctional composite prevents the adherence of one phase with others and thus results in an inefficient polymeric composite. Similarly, the second essential characteristic of the multifunctional composite is its integration in the properties. The multifunctional composite is the synonym for the multi-purpose materials, which means that a single material can exhibit different properties when exposed to different responses or conditions. The synergic behavior of the composite supports the multifunctional nature of the composite. The synergy in the conductivity of the matrix and magnetic nature of the reinforcement allows the tuning of the rheological properties of the composite. The final criterion which defines the multifunctional nature of the polymeric composite is its stable interphase. The interphase between the matrix and reinforcement should be thermodynamically stable.

Need and Purpose of the Multifunctional Polymer Composite

Multifunctional polymeric composite shows the sequence of simultaneously switch properties. These kinds of systems improved the performance of the base resin and embedded the system with various properties. These composite materials allow the integration in the properties of the matrix and reinforcement and thus impart the enhance multiple properties in the primary structural feature of the composite. They have the potential to impart any features such as magnetic, electrical, thermal, appearance, and response to that material, which does not constitute inherently. The development of such multifunctional material enables us to prepare utterly new polymer binary materials that have better properties than that of the conventional composite materials.

Classification of the Multifunctional Composite on the Basis of their Application and Properties

The functionality in the polymeric composites was broadly categorized based on their response to stimuli and applications. Fig. 2 represents the class of the functionality associated with the multifunctional polymer composite.

Fig. 1 Fundamental criteria for the multifunctional polymer matrix composite.

Fig. 2 Nature of functionality associated with the multifunctional polymer composite with their applications.

The multifunctional polymer composites exhibit the combination of the explained properties with high structural stiffness and strength with small values of density. The mechanical based properties combination included the observance of the high strength base material at the adverse condition of temperature and environment. The second class of the which exhibit multiple properties in composites was governed with stimuli-responsive polymer composites. Stimuli-responsive polymer composite rapidly changes their configuration, dimension, or physical properties with small changes in the appropriate stimuli such as heat, pH value, electricity, light, pressure, biochemical, magnetic field, solvent, moisture/water. The third category defines those multifunctional composite which exhibits the inherent strength properties of the material with its excellent thermal stability. This class comprises of those materials which have excellent thermal stability, thermal conductivity, heat absorption tendency, and ability to define the thermal fracture within the structure. The fourth class of multifunctional composites has exhibits the enhanced electrical properties in a combination of chemical stability and strength of the material.

Multifunctional Polymeric Matrix Composite for Mechanical Applications

Multi-functionality polymer composites possess many superior properties such as high-specific strength/stiffness, excellent corrosion resistance, good durability, etc. and thus, they have a considerable potential to be an alternative for the conventional mechanical and constructional base material like steel and concrete. Multi-functionality is the composite reduction in weight, volume, and cost of the mechanical/construction base devices such as girders, beam, king posts, columns and mechanical devices such as like bearing, flywheel, chucks-pin, gear key. All of these forms are used in mechanical and structural applications, but significantly the fibrous and laminates forms are more preferred because of their low density and high design stability.

Structural Component

The structural component requires excellent load-bearing, vibration absorption, and stable dimension properties with low density. The practice of achieving all of these properties in one composite is challenging. Generally, the fiber base composite system implies such properties and thus widely used in the bridge, chains, and road post design. Polyolefin based multifunctional composite exhibits all of these properties, the carbon-based reinforcement like graphene, carbon fiber, and carbon black increases the modulus of the polyolefin systems at minimal doses. This reinforcing structure occupies the interstitial sites in the polyolefin chains. It allows the force to distribute them uniformly in the structure because of which they impart excellent strength without sacrificing the flexibility in the composite. The ultimate tensile strength increased by 56% with the addition of 4% of graphene in HDPE and > 100% in tensile modulus (from 200 to 450 MPa) at 1 wt% graphene loading. HDPE has a linear structure, and the

Fig. 3 TEM images and mechanism of the graphene dispersion in the polyethylene – HDPE and LDPE. Reproduced from Wei, P., Bai, S., 2015. Graphene composite with high exfoliation and high mechanical performance via solid-state shear. *RSC Advances* 5, 93697–93705. doi:10.1039/C5RA21271E, with permission Copyright 2017, Royal Society of Chemistry.

graphene moiety acquired a patterned layer like structure, as shown in Fig. 3. The same effect was observed when the LDPE matrix is dispersed with graphene reinforcement. Filling low-density polyethylene by graphite nanoplatelets results in an increase of Young's modulus of the neat LDPE with a slight reduction of the polymer plasticity. The presence of graphene increases the thermal stability, and the dispersion mechanism imparts the incremental strength in the composite, which makes this kind of composite suitable for beam and cantilever applications.

The bridge deck and towers are made from glass fiber reinforced polyester made through the extrusion method, and the stay cables comprise of aramid parallel-lay fiber wound in the polyester matrix for excellent load-bearing capacity as shown in Fig. 4. The polymer matrix allows the stability of the bridge. It prevents crack propagation in winters, whereas the glass fiber reinforcement reduces the weight of the structure and enhance the load-bearing capacity. Similarly, the stable interphase of the composites prevents the vibration transfer within the structure (Stratford, 2012). Because of the facility of attaining the tailor-made properties in such composite, they can be used for the manufacturing of the girders with an intricate design. The combined use of carbon fiber-epoxy (C.F.) and glass fiber-epoxy layer (G.F.) was done in the design of I-shaped girders (Nguyen *et al.*, 2014). The hybridization of the glass and carbon fiber exploits the lightweight and excellent mechanical properties with high vibration absorbing properties. Whereas, the matrix increase in the chemical and corrosive resistance of the composite, which encourages their use in marine construction and temporary cross-bridges exposed to corrosive environmental conditions.

Glass fiber-epoxy with fumed silica composite extremely versatile option for strengthening reinforced concrete structures. Unidirectionally aligned glass fiber has high tensile strength and excellent durability and, therefore, it is logical to consider whether advanced polymer composite materials could be used as part of a structural column to confine the concrete. Fig. 5 shows the application of the wraps over the concrete pillar. The presence of the silica reinforcement prevents the moisture cracking in the pillar and make it suitable for the primer coating.

Sandwiched type composite has its importance in structural applications, having pre-requisite of lightweight and superior mechanical properties. The foam base laminate-composite or layer by layer structures are widely used in iso-thermal panels, support beams, temporary house walls, and pipe support systems. These systems have a core and the layer, layer transmit the applied force in all directions, and core foam reduces the density of the composites. Many of the resin such as phenolic, PVC, PET, PE, PU, and others are widely used for making the core foam base structure. In contrast, polymer-like polycarbonates, epoxy, acrylates, and others were used for the upper layer structure. Fig. 6 expresses the nature of the sandwich multi-functional polymeric composites and their types.

Fig. 7 expresses the multi-functionality associated with the application of sandwich composite in modern structures. A function-integrated GFRP sandwich roof structure for the main gate building shown in Fig. 7(a). The face sheets of this sandwich

structure have thicknesses of 6–10.5 mm GFRP, and the core is constructed using up to 600-mm-thick PU foam of three different densities in which a system of crossing GFRP webs is inserted (Keller *et al.*, 2010). The GFRP sandwich systems with ribs represented in Fig. 7(b). These composites were applicable not only for thermal insulation but also as a structural cladding for buildings (Fam and Sharaf, 2010).

Structural Ropes

Ropes and cables are defined as the mechanical component, which transmits the load in the axial direction and supports the moving or dynamic parts of the devices. Ropes comprise multiple components like yarns, fibers, filament, and strands twisted and blocked in each other in linear form. Whereas, in the case of cable, it may have sheath, wire core, cladding, and other multiple reinforcing units. Ibach Bridge in Lucerne Switzerland is the first known structure with actual utilization of the multi-functional composite in cable and rope form. The ropes and the support system of the bridge are made up of polymer matrix reinforced with carbon fiber. The mechanical properties of the carbon fiber over the axial direction are excellent, and because of which, the unidirectional carbon fiber composites acquire 60% strength of carbon fiber in the composite, which is nearly similar to the ultimate tensile strength and modulus of the steel cables. The presence of the carbon fiber imparts low-density properties in the composite ropes.

In contrast, the selection of the suitable polymeric matrix prevents the supporting structure for corrosion and abrasion without sacrificing the flexibility of the composite. Because of its flexibility, such multi-functional composite can form in various arrangements like- lamella, strip loop, rod, twisted loop, and leadline profile. The Neigles carbon fiber reinforced footbridge is the first suspension bridge with multi-functional composite cables in the world. The initial footbridge was constructed with steel

cables. However, due to the severe corrosion, the main steel cables were removed and replaced with CFRP cables. **Fig. 8** shows the structural design of the bridge with the CRPF cable arrangement (Liu *et al.*, 2015).

The multi-functional nanocomposite also contributes to the construction cable application. Carbon nanotube-PVA based cables have excellent flexibility with super stretchable nature, and thus these composites are the best candidates for the pillar padding and river defense devices. Stated carbon nano-tube and PVA composite cables have the maximum tensile strength between 350 and 380 MPa similar to spring and tensile strain in the range of 220%–250%. **Fig. 9** indicates the spring-like behavior of the cable formed with carbon nano-tube reinforcement. The free helical structures based on CNT fibers have been shown to possess the desirable stretchability. At the same time, the PVA matrix prevents the wrinkling effect in the composite, and thus, it makes the composite desirable for force damping or absorbing application in construction industries (Liu *et al.*, 2017).

Mechanical Devices

The mechanical devices include industrial dryers, separators, transmission units, spacers, heat exchangers, bushings, fitting units, etc. All of these applications are exposed to a large amount of mechanical force, torque, impulse, and vibrations. Recently, most such devices comprise of the multi-functional polymer composite. Polymeric composite acquires all of the required properties. On top of it, they have low density and excellent tribological properties. This makes the device light and easy to transport, ship, and install in the prescribes space of utility.

The 40% nylon 6 fiber-filled polyoxymethylene composite has excellent dimensional stability with a low thermal expansion coefficient and widely used in the gear application. Still, because of the susceptibility towards wear and abrasion, such gears are

Fig. 10 Illustration of the epoxy reinforced with nano expanded graphite and paraffin composite. Reproduced with permission Copyright 2017, Elsevier.

Fig. 11 Design of Epoxy bushing reinforced with PTFE fiber layer and glass fiber layer.

only limited to the small size and power transmission within a small range. Reinforced nylon 6/6 with 20% short glass fiber imparts excellent wear and tear resistance in the injection-molded gear. Still, because of the suitability toward the moisture absorption, such gear applications are limited to controlled atmospheric conditions. Polyoxymethylene matrix reinforced with PEEK and glass fiber resolve the problem and provide excellent tribological, mechanical, and structural properties to the gear with dimensional stability under normal conditions. Fig. 10 shows the composition of the gear and the structure of the PCM in the epoxy expanded graphite matrix (Wang *et al.*, 2017).

In the composites, the paraffin and expanded graphite are uniformly dispersed into the network of epoxy resin, which acts as a latent heat storage material while the epoxy resin as a supporting material which provides stability to the transmission system. Multi-wall materials like nanorods, nano-tubes, and layer structural also help to enhance the properties of the composite. One of its examples is multi-wall carbon nano-tubes (MWCNTs) reinforced polyphenylene sulfide. Polyphenylene sulfide (PPS) with acid modification is reinforced with multi-wall carbon nano-tubes, short carbon fiber, and graphite. The composite was manufactured through the extrusion process and formed into the shape of bearing through injection molding operation. The MWCNT increases the thermal suitability of the composite and restricts the radial thermal expansion in the bearing. The graphene allows the self-lubrication in the bearing with the imposition of the mechanical strength.

As of the short fiber reinforcement, the continuous fiber reinforcement allows a higher fiber volume fraction and results in a much higher load-bearing capacity than the short fiber reinforced alternatives. Because of which the composite for device bushes requires the design of such a multi-functional system that qualifies the fundamental need of the mechanical bushings. Bushings majorly comprise two distinct layers, as shown in Fig. 11. The primary layer consists of a high-volume fraction of glass fibers, and

the second layer is made of PTFE- and other polymer fibers. The first layer has a function of embedding the excellent mechanical properties in the composite and prevent the bushing from the radial deformation. Whereas, the secondary of the PTFE imparts low coefficient of friction. Both of these layers are encapsulated within the epoxy matrix. The interaction between the two layers allows the absorption of the suddenly applied force and increases the impact resistance of the composite with prevention to edge loading and misalignment. The PTFE fiber layer increases the inertness of the structure and provides excellent resistance to bushing form corrosive media. The epoxy matrix and the first layer of the structure absorb the noise and vibrations. Because of this, the bushing can sustain with bearing capacity under low sliding speeds (less than 0.01 m/s) can be up to 150 MPa.

Self-lubricating polymer composite with excellent mechanical properties components is often needed in machine systems in which no external oil or grease lubrication is acceptable. One example is the use of sliding shoes in textile dryers. To such an application, the polycarbonate filled with PEEK and graphite flakes with PTFE additive system shows excellent toughness and with continuous loop sliding strength without any deformation in the composite.

Other

- (1) *Smart roofs*: The multi-functional composite of an epoxy matrix reinforced with jute and glass fiber is widely used in the design of the smart roofs. The long jute fibers were impregnated with the woven sheets of glass fiber cured with silane-modified unsaturated polyester resin. The 15% randomly dispersed jute fiber enhances the noise-damping properties of the roof, whereas 15% of the woven mat of glass fiber incorporates the thermal insulation in the roof (Aly-Hassan, 2015). In contrast, the hydrophobic or snow repellent functionality is induced by the modified unsaturated polyester matrix. In addition to it, the hybrid of the random and woven arrangement of the fiber encourages the uniform distribution of load within the structure.
- (2) *Pipe Coatings*: Polypropylene matrix reinforced with expanded graphite composite have excellent mechanical properties with high abrasion resistance towards soil particles and have the capability if machining such composites are widely used in onshore pipe coatings.
- (3) *Desalination membranes*: Polyaniline and carbon nano tubes-based composite was deposited over the fabric, which provides the membrane for desalination. The electroactive property of the matrix and the mechanical stability of the carbon nano-tubes enables the composite for ion electro-sorption and storage.
- (4) *Electrostatic discharge proof mechanical devices*: CNT-filled conductive ABS nanocomposites, finding a low CNT concentration for electrical conduction (0.75 wt%), though limited to a much lower final nanocomposite conductivity of 10 – 5S/m, suitable for ESD protection applications.

Multifunctional Polymeric Matrix Composite With Stimuli-Responsive Application

Stimuli-responsive polymeric composite reveals multiple properties that are governed with switch effect. The switch for expressing the property is called stimuli, and the change in properties of the polymeric composite is termed as the response.

So, the polymeric material which reciprocates the stimuli with a change in their physical or chemical properties falls under this class of material. Broadly the response is classified in physical and chemical classes. Fig. 12 depicts the relation of stimuli and response with the state of composite (gel, solid, surface, and liquid). In such polymeric composites, one can achieve one or more synergic response by multiple stimuli, or multiple stimuli through single stimuli.

Sensors

Modern industries comprise the challenging process where efficiency, nature, and safety are the key aspects. In such a challenging process, the evaluation of its sustainability will not be possible in the absence of smart composites. Such smart composites are widely used in sensors application because of their three fundamental properties (1) Ability to sense the stimuli in adverse environmental conditions, (2) converting stimuli in response in the real-time interval, and (3) making actuation by moving away from or to the stimuli. Because of these three attributes, such smart composites are widely used in sensing and monitoring of structure health, drug delivery in humans, gas sensors, fire safety alarms, chemical processing flow meters, humidity sensors, etc. The first thermal sensor-based composite was introduced commercially in the form of fluorescent thermometers. Fluorescent thermometers contain polyacrylamide matrix incorporated with metallic nano-particles and 4-N-(2-acryloyloxyethyl)-N-methylamino-7-(N, N-dimethylamino)sulfonyl-2,1,3 benzoxadiazole pigments. The metallic nano-particle allows for enhancing the thermal conductivity of the system. By sensing the temperature, the polyacrylamide chains undergo the LCST transition and allow the pigment to participate in the molecule conjugation. As a result, the pigment shows the change in their color, and by sensing that change, the temperature was recorded.

The layer by layer multi-functional composite of polyurethane (PU)- single-wall carbon nano-tube and poly(3,4-ethylene-dioxythiophene) (PEDOT) polystyrene sulfonate(PSS)-single-wall carbon nano-tube exhibits excellent transparency, stretchability, and response to strain. The sensor acquires 112% elongation, 62% optical clarity, and GF ¼ 62 high sensitivity. This strain sensor can be used to detect the emotional expressions, such as laughing and crying, by attaching it to the face of the human.

Fig. 12 Relation of stimuli and response with the state of composite.

An interesting example is a sensor in which poly(*p*-phenylene vinylene) was used as a dye. The dye was incorporated in LDPE through the melt-encapsulation method. The LDPE was filled with talc nano-particle as the particulate reinforcement. The added dye showed the stress damage area when the sample was characterized by luminescence during stretching in the universal testing machine. The talc particle creates the epicenter for the force transmission in the LDPE matrix, and this force transmission allows the breakage of the dye encapsulation. Because of which the composite indicates the stress damage in the structure.

Smart composites or multi-functional responsive polymeric composite also considered as an excellent choice for biosensors. Biosensors are the monitoring devices that detect the chemical substance or biological with the human, animal, and plant body and record the change with the help of physicochemical detectors. In modern health technologies, such sensors are the game changers in many applications. For example, composite of Fe_3O_4 – poly(Indole-*co*-thiophene), where magnetic Fe_3O_4 is in a particulate nano form, provides the center for electromagnetic sensing and matrix poly(indole-*co*-thiophene) allows the conductivity of the signal through it. Such a stimuli-response base composite is widely used in the hemoglobin diagnostic biosensor (Rouhi *et al.*, 2016). In the sensor comprises of the carbon paste electrode modified poly(Indole-*co*-thiophene)- Fe_3O_4 nano-composite, the composite immobilizes the hemoglobin in the blood by responding through the change in electrical signals. **Table 1** represents examples of polymeric and reinforcing systems used in the biosensor applications.

Shape Memory Application

The original phenomenon of shape memory was established with the martensite, and that is the reason it is also termed as martensitic transformations. In a polymer, these effects can be seen because of the interaction of the crystalline and amorphous phase. Such polymer matrix composites exhibit a unique property of showing transformational responses, when subjected to heating, exposed to light, on the application of pressure, placed under an electric and magnetic field, as shown in **Fig. 13**.

The shape memory polymer composite act as smart materials possessing a tendency to regain their original permanent or partially deformed shape on the application of external stimuli in the form of heating, electric or magnetic field, or by light stimulation. The effect of the shape memory can be seen by determining the bending, shrinkage, and deformation in the composite when exposed to stimuli. For example, the composite of cross-linked polyethylene and silica particle shows large deformation when subjected to heat stimuli. Similarly, after removing the stimuli, the composite shows equivalent recovery in the structure. Because of such multi-functional of the composite, they are readily used in the electric wiring, shrink film, and conduct application. The multi-functional composite of poly(caprolactone) (PCL)/polyurethane (PU) blend with graphene nanoplatelets reinforcement shows the shape memory effect for light and electrical stimuli. **Fig. 14** shows the graphical abstract of the shape memory effect in PCL-PU/graphene composite. The graphene molecules allow the light and electrical actuation in the composite. In contrast, the presence of PCL interferes with the crystallinity of the matrix in combination with the soft and hard segment of the

the balanced cross-linked and linear phase, the composite offered 96% recovery to its permanent shape. **Table 2** express the nature of matrix and reinforcement used in the shape memory composite for a specific application.

Smart Packaging

Packaging enhances the shelf life of any product by protecting the product against deteriorative effects caused by exposure to and interaction with the external environment. To satisfy the need of the consumer in the present world, packaging industries have to rely on active, stable, and intelligent packaging structures and materials. Those a packaging system that is capable of carrying out intelligent functions (such as sensing, detecting, tracking, recording, and communicating) to facilitate decision-making to extend shelf life, improve quality, enhance safety, provide information, and warn about potential problems are classified as “Smart packaging”.

Polyacrylate based composite reinforced with anthraquinone-2-sulfonic acid-modified hydroxypropyl cellulose will act as sensing ink for oxygen emission. **Fig. 15** shows the prototype of such a device, where the ink over the label having polyacrylate/cellulose composite fades out with a decrease in the freshness of the product. Temperature responsive polymeric composite like thermoplastic polyurethane-modified talc are materials with great importance in cases of meat, dairy products, and frozen food storage.

Additionally, the rate of Physico-chemical and microbiological changes is highly dependent on temperature values. During storage, the changes in metabolite concentrations such as glucose, amine, ethanol, organic acid, CO₂, TVB-N, adenosine triphosphate degradation products, and biogenic amines indicate spoilage of meat products. Likewise, in the meat storage packaging, the detection of volatile amine can sense the spoilage of the meat. Polyethylene terephthalate- PET fiber base composite added with metalloporphyrin has a wider range of applications in the meat packaging sector. Such indicators observed the volatile component and then convert the gas stimuli into color response (Biji *et al.*, 2015).

Moisture is the other important factor responsible for food spoilage; it provides a bacterial friendly atmosphere, and thus bacteria reproduce in such atmospheres, so to increase the life of the food, it is very important to suppress the water activity in the product. For example, the cheese and candies packaging uses the PP/Talc/molecular sieve base composite structure, which increases the life of the product by 30%. In many of the cases, sandwich laminates of polymer and metallic layers are also used. Still, because of limitations in their recycling, such laminates are not part of the sustainable technologies.

Milk packaging has been newly developed to evaluate the degree of milk spoilage during storage, mainly due to increased demands on product safety, shelf-life extension, and customer convenience. Nowadays, multi-functional polymeric composite layers or laminates are widely used in this are the composite of PP and ion-exchange resin-modified clay exhibit the spoilage sensing capabilities in milk packaging. Quaternary alkylammonium cations treated clay sense the pH change in the milk and thus respond to this change by converting its color from green to yellow (Tassanawat *et al.*, 2007).

Others

Self-healing

Polymer composite with multi-functional properties exhibits tremendous application in the engineering field under adverse environmental conditions. Because of the continuous exposure to such harsh conditions, many of the polymeric composites are susceptible to micro-cracking and brittle failure. To avoid this failure, such composites are required, which can repair the formed crack inherently, and such composites are called as self-healing composites. The stimuli can be of redox, thermal, light, magnetic, etc. but the response mechanism complies with the filling of the micro-cracks and cause healing of the composite. For example, polyvinyl butyral (PVB) composite having a 3-Nitrosalicylic acid monomer having redox-sensitive polyaniline (PANI) shell. This composite system was coated over zinc panel, when shell senses corrosion, the PANI shell switch from impermeable to permeable when there is a change in potential concurrent, to release the active agents in the crack, because of which the monomer start polymerizing within the crack (Vimalanandan *et al.*, 2013). Similarly, epoxy composite with hexamethylene diisocyanate filled polyurethane capsules senses the tribological stimuli or wear and tear failure. The wear and tear in the capsule allow the release of the monomer to cause repair of the crack (Khun *et al.*, 2014). A hybrid carbon-fiber/epoxy composite reinforced with self-healing core-shell nanofibers at interfaces was fabricated by co-electrospinning, where the healing agent DCPD was encapsulated into polyacrylonitrile (PAN) to form core-shell DCPD/PAN nanofibers activated by heat.

Drug delivery

In recent years, pharmaceutical research has focused in field of drug delivery. Currently, the use of multi-functional polymer composite represents an alternative system with a huge potential for the targeted distribution of drugs or biological macromolecules in the body. Magnetic nanoparticles based polymer composites are sensitive to the external alternating magnetic field. It is used frequently in nanocomposite to control drug release. Poly(lactide-co-glycolide acid) microparticles loaded with both insulin and magnetite nanocrystals. The magnetic particle guides the drug under the influence of the magnetic field in the area of the small intestine and helps to control the blood sugar in the body.

Chitosan reduced graphene oxide nanocomposite was prepared through a reduction process and was used in the transdermal drug carrier system. The reduced graphene enhances the electrical conductivity of chitosan and makes the nanocomposites useful for electroporation or iontophoresis drug delivery applications.

Similarly, the UHMWPE-CNT composite has the capability of loading and release the drug to the targeted area. CNTs reinforced PE composite surface is modified through chemical etching technique. Etching causes the creation of porous structure in the polymeric matrix; these interconnected micropores provide the space for the drug accumulation and allows the acetabular cup to release the drug on the targeted area.

Ag/carboxymethyl cellulose-poly acrylamide hydrogel nanocomposite has biodegradable behavior. They have studied the nanocomposites with diclofenac sodium (DS) as a model drug to assess the release characteristics. According to the research outcome, the synthesized matrix has shown safe transmission of drugs through the stomach (high acidic environment) without any alterations and efficient release of drug components under the basic environment of colon.

Composite of polylactic acid- poly(ethylene oxide) imbedded with polysaccharide base microcapsule carrying bromelain drug detects the change in enzymatic atmosphere and delivers the drug to the targeted area. Clay-based reinforcement also expresses application in the drug delivery segment. Aluminosilicate in the form of halloysite nanostructure dispersed in the hydrogel of sodium hyaluronate (SA)/poly (hydroxyethyl methacrylate) and embedded with the anticancer drug is widely used for treating spot cancer.

Multifunctional Polymeric Matrix Composite With Thermal Application

Fire-Safety Devices

Multi-functionality in polymeric matrix composite enables their use in critical applications where the material has to sustain the strength in the adverse condition of temperature and environment. Although, the fire resistance of such composite alarms the severe safety issues. All of such composites have polymeric matrix, vulnerable to combustion when exposed to direct contact of fire. To incorporate the flame retardancy in the composite mainly, two approaches are implied – (1) modification of polymer matrix/fiber with flame retardant functionality and (2) Addition of the flame-retardant additive in the composite systems. Both approaches are based on the elimination principle. The main aim of this principle is to eliminate any of one entity required for the combustion.

For example, Metal oxides and hydroxide modification in composite follows the heat sink mechanism and suppress the heat gradient because of which arrest the combustion in the composite. Boron based modification forms the char around the composite and eliminates the air supply required for the combustion. The synergistic base modification allows the combination of char formation of gas-phase to eliminate the air and direct contact with the fuel. The grafting of polypropylene with acryl-amide (AAM) enhances the flame retardancy in the composite. The acryl-amide allows the formation of char when it comes in direct contact of fire and prevents the burning of the plastic.

Similarly, grafting of brominated monomer either on the polypropylene matrix or on glass fiber by polymerizing around the Sb_2O_3 particles or onto both. In continuation of the grafting, the metal oxides were also incorporated in the system, which increases the flame retardancy properties of the composite. The phosphorus moieties were incorporated in the main chain of PET, and the composite was reinforced with glass fiber. Glass fiber enhances the thermal management capabilities of the composite. In contrast, the presence of phosphorus in the main chain suppresses the burning tendency of the composite. It was observed that GF-PET composite achieved V-0 rating in the UL94 test when 15% FR-agent was added while the LOI increases linearly with increasing FR-agent add on up to 26% where it achieves an LOI value of 32. In addition to this, the glass fiber also increases the tensile modulus of the composite. It fits the composite for potential applications in devices like electrical laminates, sparks plug casing, and in other electrical applications. Carbon microspheres also impart the flame-retardant nature in the PET matrix.

The flame-retardant nature of the composite is also acquired by grafting inorganic salt on the main chain of thermoplastic polymer and reinforcing the polymer with inorganic filler like glass fiber and carbon fiber. The inorganic salt like include alkaline earth salts and alkali metal salts decompose at elevated temperatures to produce an insulating and adherent char on the polymer surface that provides fire protection. In addition, the decomposition reaction of the salts produces a significant amount of carbon dioxide that serves to quench the flame. The typical example is ABS composite, ABS is added with 21% sodium methacrylate salt through graft copolymerization method. Because of the flame-retardant moiety present in the main chain ABS the time-to-ignition of the composite increases by 161% (Suzuki and Wilkie, 1995).

Thermoplastic like polystyrene, PP, and polyacrylonitrile matrix can be incorporated with Silicon-methoxide-modified clays reinforcement. The linkage between the silicon and clay occurs in the clay. Still, it is not likely to occur in the nanocomposite, perhaps because of the presence of the polystyrene increases the distance between the reactive sites and the cation cannot span this distance, which decreases the heat release rate of the composite and made it more suitable for electrical and automobile applications (Zhu *et al.*, 2002).

A new type of epoxy composite was made by cross-linking diglycidyl ether of braided carbon fibers (CFs) and bisphenol A-epoxy matrix modified by phosphoric acid. The phosphorus acid in the structure of modified epoxy allows the formation of a condensed phase and reduces the total heat release in the combustion. The flame-retardant nature in the epoxy can also be incorporated by reinforcing the matrix with graphene nanosheets (GNs) modified by molybdenum disulfide (MoS_2). Compared with neat epoxy, the thermal stability of $\text{MoS}_2/\text{GNS}/\text{Epoxy}$ composites with 2.0 wt% MoS_2/GNS mass fraction was significantly improved, initial decomposition temperature increased by 53°C . HRR and THR decreased by 45.8% and 25.3%, respectively, and the TSR was reduced by 30.5% (Wang *et al.*, 2013).

The combination of clay and carbon nanotube is also one of the most widely used flame retardant reinforcement for the epoxy matrix. Fluorinated montmorillonite with multi-wall carbon nanotube -epoxy composite exhibit gas phase mechanism of the flame retardancy. The thermal insulation of MMT and the high specific heat of MWCNT hindered the heat transfer of EP. The char yield increased from 9.1% to 15.4%, and LOI grew from 21% to 31% due to the influence of flame retardants.

Aerospace Application

Aerospace industries demand the development of such material that can sustain its property in an adverse environment of space without any deformation. In addition to it, the material should have low density so that it not affects the carriage capacity of the launch vehicle and thus multi-functional polymeric composite are the best suitable option which can sustain its properties when exposed to high vacuum, ultra-high or low-temperature cycle effect, ultraviolet (UV) radiation and ozone saturation conditions. Carbon fiber and polyether amide matrix-based composites added with graphene nanoparticles are progressively being employed in spacecraft and aircraft industry because of remarkably high strength, modulus, lightweight, good fatigue life, high stiffness, and excellent corrosion resistance. Similarly, thermoplastic polymer matrix like aromatic polyimides is known to have excellent properties such as high dimensional stability, low thermal expansion, and outstanding thermal and environmental stability due to

Fig. 16 Structure of BECFRP composite used in satellite camera mounting.

which such matrix base composite are widely used in the rocket grid, fuel tank casing, jointing of the aircraft laminates and in the fuel cell or batteries.

Polyetheretherketone (PEEK)-carbon fiber-based laminates show excellent mechanical properties with extensive heat resistance capabilities. The advantages of PEEK material over traditionally used CFRP material are in terms of lightweight, low surface root means square (RMS) error and its applications for reconfigurable space antenna (Kalra *et al.*, 2019). PEEK matrix base composite can save between 10%–45% in the overall weight of the structure. In addition to it, PEEK has a low thermal expansion coefficient as compared to aluminum and thus suitable for high-frequency band antennas with high surface accuracy. Ultra High Molecular Weight Polyethylene (UHMWPE) with glass fiber-epoxy. The composite produced gives excellent shielding and protection against chlorine-based radiations along with enhanced mechanical properties of structural blanket applications. Thermal blankets are essential for regulating the temperature of most spacecraft. PVDF filled silica nanoparticle-based composite has excellent chemical inertness. The cross-linked matrix of vinylidene fluoride (PVDF) has been developed for wire and cable insulations for high radiation environments. Applications include RTGs (Radio-isotope Thermal Generators) and high radiation environments such as Jupiter orbiters.

The blankets consist of a polymer film that is either, (1) filled with carbon black pigment to absorb sunlight, or (2) coated with a layer of vapor-deposited aluminum to reflect sunlight. The layers are made up of polyethylene terephthalate and polyimides separated by fine scrim cloths made from polyamide. The thin layer was reinforced with indium tin oxide particles and sandwiched with carbon fiber reinforce the elastomer system. The indium tin oxide particles dispersed in the matrix allows the dissipation of static electricity throughout the structure when subjected to the ionic environment at high temperature, fine polyamide scrim helps in heat dissipation and the rubber sandwiched layer enhances the flexibility in the structure (Willis and Hsieh, 2000). The same layer by layer adhesion principle is also applied to barrier-enhanced carbon fiber reinforced plastic (BECFRP) (Anguita *et al.*, 2019). In such a multi-functional composite, the reinforcing layer is allowed to diffuse within the matrix layer. The diffusion involves unique methods like etching or plasma exposure, which matches the stress on the surface of the reinforcement with the matrix. stress-matched surface reduces the stresses and contamination at the surface, resulting in stronger adhesion and mechanical integrity, even after thermal cycles. This layer was then integrated with the barrier layer through the sandwich mechanism and thus improves the strength of the material. Fig. 16 presents a cross-section of the coating after deposition on a CFRP surface that is highly structurally featured with protrusions with a radius of curvature of 1–2 μm with the typical layer by layer structure of BECFRP for the better understanding of the concept. The other major component of the satellite is its receiver and transmission disc.

The multifunctional polymeric composite also caters to the design market of airplanes, jets, and space crafts. Glass, carbon, and Kevlar fiber composites have been routinely designed and manufactured for aerospace parts. The aerospace industry primarily uses carbon fiber composites because of their excellent mechanical and thermal properties. In addition to this, such material exhibits high weight-saving properties with excellent dimensional stability. The application requires the sustainability of the material within -100 to $+100^\circ\text{C}$ (low earth orbit). To which the epoxy-PU laminate with hybrid (carbon and flax) fiber reinforcement composite complies. Table 3 express the application of multi-functional composite in the aircraft and jet parts with their multi-functional nature.

Recently, the polymeric matrix multi-functional composite was explored in the realm of ablation composite. Ablation composites are those composites which often used as the sacrificial materials. Phenolic resin/asbestos cloth/layered silicate nanocomposite also showed excellent ablation properties. At $9 \times 10^6 \text{ W/m}^2$ external heat flux and 3400K temperature of hot gas conditions, the effective thermal diffusivity of resol type phenolic resin-asbestos cloth composite and montmorillonite layered silicate nanocomposites. The composite shows the formation of the sacrificial layer of resol when subjected to the high heat flux (Fig. 17).

Table 3 Multi-functional composite used in the aircraft and jet parts

Sr. No	Matrix phase	Reinforcement phase	Application	Properties	References
	PVDF modified Epoxy	Short glass fiber	VOR antenna	● EMI shielding ● Excellent dimensional stability ● Good deflection properties	(Mahdavi, 2017)
2	Epoxy	Phenolic coated aramid fiber paper, Carbon Fiber	S-Ducts	● high strength to weight ratio ● Excellent resilience ● Insulation properties	(Ghori <i>et al.</i> , 2018)
3	Comingled thermoplastic Or ABS	Carbon fiber and graphene	Main landing gear	● Excellent tribological properties ● Good shock absorption	(Ghori <i>et al.</i> , 2018)
4	Bismaleimide	Polyimide honeycomb structure	Leading-edge radome	● Lightweight ● Excellent abrasion resistance ● Thermal stable at low temperature	(Fischer, 2016)
5	Epoxy/polyimide PMR – 15	Carbon/Kevlar fiber	Inlet housing	● Thermal resistance upto 400°C ● Heat dissipation properties ● Excellent cracking resistance	(Sun <i>et al.</i> , 2019a)

Fig. 17 Phenolic resin/asbestos cloth/layered silicate nanocomposite ablation performance under oxyacetylene flame. Reproduced from Bahramian, A.R., Kokabi, M., 2009. Ablation mechanism of polymer layered silicate nanocomposite heat shield. *Journal of Hazardous Materials* 166, 445–454. doi:10.1016/j.jhazmat.2008.11.061.

Specialty polymers like poly(phenyl silylene) and polyphenylene have excellent heat resistance and ablate at a higher temperature. Because of which the carbon fiber and glass fiber added composite of such matrix have potential use in the heat shield applications. The poly(phenyl silylene) has reactive -Si-H and -C-C- triple bond, therefore, it is cross-linked above 150°C by hydrosilylation reaction between -Si-H and -C-C- triple bond which result in limited mass loss.

Heat Exchangers

Metals and alloys like iron, steel, copper, etc. are widely used as the material of construction for different heat exchangers because of their excellent thermal conductivity and heat dissipation factor. However, they are prone to fouling and corrosion because of which such structure requires frequent maintenance and changing of assemblies. To resolve this issue, polymeric matrix composite is widely considered because of its excellent fouling and corrosion resistance, ease of manufacturing, ability to handle liquid and gases and weight, space, and volume savings.

Composite of linear low-density polyethylene (LLDPE) filled with aluminum nitride particle shows thermal conductivity three times higher than the pure LLDPE. The aluminum nitride particle dispersed in the LLDPE facilitates the localization of heat absorption and then dissipates the heat throughout the composite structure. In contrast, the LLDPE matrix allows the incorporation of flexibility and hinge-ability in the composite structure. Hence, for such composite, the concentration of the aluminum nitride is the key entity to fine-tune the thermal conductivity. To further increase the heat exchange properties of the system, polyphenylene sulfide filled with spherical hexagonal boron nickel. PPS matrix exhibits excellent resistance to acid attack. It has not been found to dissolve in any solvent at temperatures below about 200°C , because of which it is widely used for such chemical unit operation where the heat exchanging fluid is corrosive in nature (Leung *et al.*, 2013).

Recently, vapor grown carbon fiber (VGCF) base polymeric matrix composite is of significant interest in heat exchange application. The addition of VGCF in the epoxy matrix enhances the thermal conductivity of the composite and allows the use of such composite for electrical heat exchanging devices (Chen and Ting, 2002). The carbon nanoparticle filled polylactic acid (PLA), and polyamide 12 (PA 12) base matrix composites were selected as replacement of copper absorbers. The PA 12 and PLA matrix have excellent mechanical strength and flexible in nature, whereas the addition of 5% carbon nanotubes in the polymeric matrix with carbon fiber enhances the thermal conductivity by 25% in the composite. To reduce the thickness of such multi-functional composite, the coating routes are widely explored, it comprises of the coating of the multi-functional composite on to the metal substrate or inside the metallic tubes used for heat exchanging operation.

The coating route facilitates the use of thermal conductivity of the metal and the inner composite coating prevents the fouling and corrosion of the tube. The coating of nickel-copper-phosphorus-polytetrafluoroethylene (Ni-Cu-P-PTFE) composite coatings on stainless steel substrates are some typical examples. Ni-Cu-P-PTFE composite coatings imply excellent hydrophobic nature. The PTFE matrix prevents the fouling and cavitation inside the tube when delivered with salt water, and the addition of copper to the Ni-P moiety is found to improve the corrosion resistance of the coatings. Polymeric hollow fibers base composite are also widely used in the heat exchanger films and panels. The polymeric hollow fibers incorporated in the PEEK matrix for surface heat exchanging in the fins. The plate heat exchanger has the PEEK film sandwiched between two metallic frames and reinforced with hollow fibers of PE or UHMWPE. The hollow fibers entrap the air in the hollow moiety and increase the heat transmission efficiency of the heat exchanger (Christmann *et al.*, 2013).

Others

Pressure vessels and chemical reactors

The fundamental criteria required in selecting the materials for chemical reactors and vessels are: (1) chemical inertness in the material (2) excellent mechanical strength, (3) excellent thermal resistance, and (4) excellent resistance toward crack propagation. All of such properties are difficult to acquire in the single material. Thus multi-functional composites are considered to be an excellent option for construction materials for pressure vessels and chemical reactors. For example, the use of silane-modified epoxy/ carbon fiber composite in the construction of the cylindrical pressure vessel. The long carbon fiber was matted in the single yarn and then dipped in the modified epoxy resin before forming over the cylindrical core. The epoxy-coated carbon fiber yarn was wound over the cylindrical pattern at 15° longitudinal tows in the first step, and then the winding is done at 90° hoop tow. Because of the overlapping of the winding, the composite creates an excellent intact structure, and thus the thermal and mechanical stresses get uniformly distributed throughout the structure. As a result, the cylinder or reactor can sustain a high-pressure reaction (Shao *et al.*, 2016).

For many hydrogen containment vessels, the fiber wound composite of high-density polyethylene (HDPE) and glass fiber dipped in unsaturated polyester are widely used. The HDPE/silica is used as a material of construction of the liner. The compounded composite of HDPE and silica was molded into the desired shape of the liner through rotational molding. After the continuous glass fibers, yarn dipped in UPR was wound over the HDPE liner. The winding is done over the 15° longitudinal tows and then at 90° hoop tow (Nunes *et al.*, 2010). The HDPE liner provides dimensional stability in the structure and contains the hydrogen to prevent its direct contact with the UPR-glass fiber. Whereas the glass fiber helps in the enhancement of the thermal resistance of the structure, and the binder (UPR) will distribute the mechanical force in all directions and thus increase the bursting strength of the vessel.

In industries, many of such applications are presents which demand the storage of the low-temperature liquid or need cryogenic storage tank or vessels. For such an application, the composite of PEEK and nylon fiber/carbon fiber hybrid composites were considered. PEEK matrix has the capability of containing corrosive liquid at low temperature without any swelling of liquid or gas migration. Due to which the liner of such vessels was produced with PEEK material added with talc nanoparticles. Talc nanoparticles occupy the interstitial sites of the PEEK matrix and enhance the migration resistance of the composite.

Petroleum pipes

Fiber-based polymeric composites are widely used in the pipes used for the transportation of oil and natural gases. Mainly the glass fiber and carbon fiber reinforcement are widely used in such pipes with thermoplastic and thermosetting matrix. GFRP pipes have a high strength to weight ratio. They are considerably lighter than steel or concrete pipes of comparative strength and also exhibit excellent resistance to abrasion. Due to which the glass fiber reinforcement is more popular than that of the carbon fiber reinforcement. For lubricant transportation, the short glass fibers were incorporated within the HDPE and PP matrix and drawn in the hollow pipe by extrusion. In such a composite, the HDPE/PP matrix will resist the oil swelling in the material, and the glass fiber reinforcement allows the pipe to bear internal and external pressure without deformation. Inorganic filler materials, such as hydrated alumina, glass microspheres, clay, talc, calcium carbonate, calcium silicate, and sand, are sometimes used to increase the economic benefit and performance of GFRP pipes. But when the liquid is volatile and of low viscosity, in the condition, the hydrothermal cracking and aging in the pipe should be considered during its designing. In respect to this the epoxy and vinyl ester-based glass fiber composite pipes are deployed for transporting petroleum oil. Reinforced thermoplastic pipes are flexible and spoolable in nature, where the reinforcement continuously wound onto the thermoplastic liner. Liners currently PE, but could be PA12 or PVDF. Reinforcement is aramid, PET, or wire, usually encapsulated in a PE tape to aid application, but not impregnated. Tape may or may not be bonded to the liner. Glass or carbon reinforcement not used, as the perception is that these cannot be used in the unwetted state.

Steel pipeline repairs

Steel pipelines are widely used in convey hot liquid from one point to another point in the chemical industry. The adverse condition of temperature and pressure in the pipe leading to the development of cracks, leaks, and ruptures. At the same time, when the corrosive liquid is the transporting liquid, than the life span of the steel pipe found to be reduced. The multi-functional polymer composite can sustain such adverse conditions of pressure, temperature, and corrosion, thus suitable for such repairs. Such a pipe can be repaired with the help of different methods like – pre-cured layered system, stand-off sleeves, and infills. The pre-cured layered system involves the bonding of pre-cured fiber-reinforced composite materials that are held together with an adhesive applied—for example, the use of carbon fiber-based ultra-high temperature resistance epoxy matrix. The precured sheet of such composite was deployed over the ruptured surface and allowed to adhere to the steel. After that, a cross-layer of the composite was applied on the same layer and then allowed to cure. Aramid fiber-based composites are strongly advisable as an option of pipe rehabilitation to those areas, where the pipes are continuously exposed to the corrosive chemical. The repair heat shrink sleeve of the PE/PP matrix reinforced with thermally treated aramid fiber is widely used in the hydrodesulfurization (HSDU) plant of the petroleum industries. The petroleum refineries chemical process requires the transportation liquid and gases through pipe at elevated temperature and at such aggravate condition of temperature, the pipe inner lining becomes susceptible for cavitation and corrosion. The repair of such pipe or section of such pipe were done with the help of clay dispersed polyurethane-Kevlar fiber composite.

Multifunctional Polymeric Matrix Composite With Electrical Application

Electric energy storage system (ESS) is one of the most popular and reliable ways to store electric energy from intermittent renewable sources to ensure timely and reliable delivery of an adequate amount of electric power for portable electronic devices, electric-powered vehicles, and other applications. The electric energy storage devices comprise electrochemical batteries, solar cells, photovoltaic assemblies, and piezoelectric structures. All of these entities require durable, lightweight, functional, and high-performance base material, and thus recently, the demand for polymeric composite in such area is increasing day by day. Nowadays, such multi-functional composite is emerging, which can give a full proof solution as the material of construction for electrode, electrolyte, capacitance, and current collector in the electrochemical devices. Such advancement in the material and design increases the efficiency of the electrical storage technologies and helps in the betterment of the society.

Lithium-Ion Batteries Electrodes

Batteries are an essential class of electrochemical energy storage devices, especially lithium-ion batteries. They are prevalent rechargeable batteries and thus widely for supply power to mobile phones, laptops, electronic devices, and other portable systems like vehicles, motion communication devices, and remote location transmitting signals. The Li-ion batteries express fast charging, low density, high energy density, and low self-discharge rates but many times susceptible to leakage, rigid with their geometry, and can cause hazards. Thus, to improve the drawback of these batteries, the use of polymeric composite instead of conventional material has drawn significant research interest. Batteries comprise anode, cathode, and electrolytes, this section projects the use of

Table 4 PANI-carbon nanotube composite – Capacitance, cycle life, and properties data

Sr. No	Composite electrode	Capacitance (F/g)	Electrolyte	Cycle life	Properties
1	PANI-MWCNT (60/40) + 15% acetylene black (15 wt%) and 5% polytetrafluoroethylene	328	1 M NaNO ₃	1000	● Excellent corrosion resistance ● Dimensional stable ● Low pitting electrode
2	73% PANI reinforced with 25% PVDF modified carbon nanotube	463	1 M H ₂ SO ₄	1000	● Low volumetric expansion ● Lightweight ● Excellent charge conduction
3	52% PANI + 38% multiwall nanotube + 6% carboxy-methyl cellulose (6 wt%) and styrene-butadiene rubber (4 wt%)	606	1 M H ₂ SO ₄	200	● Low volumetric expansion ● Excellent erosion resistance
4	80% PANI + 2% carbon black + 12% graphene	574	5–6 M KOH	600	● Self-lubricating ● Excellent charge conduction

Note: Gajendran, P., Saraswathi, R., 2008. Polyaniline-carbon nanotube composites. *Pure Applied Chemistry* 80 (11), 2377–2395. doi:10.1351/pac200880112377.

multi-functional composite in all of the constituent of the batteries. The electrode -anode and cathode construction material requires excellent corrosion resistance, mechanical strength and excellent electrical conductivity in the materials. Generally, graphite, tin and silicon alloys are widely used for the construction of the anode. All of these anode binders have excellent conductive properties. Still, because of the lithiation, the anode undergoes volumetric expansion and thus the limit the use of such batteries.

The polymer with highly conjugated chains allows the motion of electron with the structure and thus causes the flow of current through the lattice. Such polymers are called as a conductive polymer, the examples of such polymer are polyacetylene (PA), polypyrrole (PPy), polythiophene (PTh), poly(*p*-phenylenevinylene) (PPV), polyaniline (PANI) and poly(3,4-ethylenedioxythiophene) (PEDOT). The incorporation of carbon nanotube into the PANI matrix is expected to enhance its electrical and mechanical properties, which are essential for actual device fabrication. Table 4 indicates the capacitance (storage ability), the life cycle of the PANI-carbon nanotube-based composite electrode used for different electrolytic batteries.

PANI-carbon nanotube composites can be used as efficient electrocatalytic materials in fuel cell reactions like oxygen reduction and methanol oxidation. The CNT provides higher surface area and better electronic conductivity while PANI facilitates the electron transfer through the conducting matrix. The dispersion of graphene oxide, reduced graphene oxide, and graphite nanoflakes based reinforcements in the polyaniline matrix have attracted considerable interest in the fields of electrochemical energy storage application, and such composite base electrodes are called as polyaniline-2D carbon composite electrode. The typical example is polyaniline (PANI)-graphene sheet (GO) and reduced graphene oxide (rGO) composite added with carbon nanotube (CNT) and MnO₂ particles to increase the capacitance value. Fig. 18 compares the specific capacitance of such composites. It was observed that the reduced graphene oxide has better specific capacitance value as compared to the graphene sheets (Sathish *et al.*, 2011).

The composite of V₂O₅ nanobelt arrays (NBAs) was directly grown on 3D ultrathin graphite foam (UGF) as shown in, and then subsequently coated by a mesoporous thin layer of the conducting polymer of PEDOT (Chao *et al.*, 2014). PEDOT based metal oxides/hydroxides hybridized composite provide the most promising performance with reduced cost and weight. For example, RuO₂/PEDOT nanotubes with a high specific capacitance of 1217 F/g and a high power density of 20 kW/kg from the high specific surface area and fast charge/discharge of the tubular structures.

The non-conductive polymer composite for electrode application follows the compounding route, where the non-conductive polymeric matrix is incorporated with conductive moieties. Such composites have easy to process nature with excellent functional properties. Electrode binders like polyvinyl alcohol (PVA), Carboxymethyl cellulose (CMC), Styrene-butadiene rubber (SBR) are widely preferred for the construction of the electrode. The binders were added with conductive reinforcement like carbon black, graphite, graphene, Carbon nanotubes, and collectors such as aluminum, nickel, Ag, Au, Pt, alloys, graphene for cathode and copper, nickel for the anode to prepare a multi-functional composite. For example, the composite of styrene-ethylene-butylene-styrene (SEBS) reinforced with HDPE added carbon fiber had been shown excellent electrical and mechanical properties. The styrene base polymer causes ease of processability and makes it suitable for electrode application. The butylene-styrene component of the matrix restricts the volumetric expansion of the anode. Whereas, the presence of carbon nanotube in the HDPE fiber impart electrical conductivity in the composite and make it suitable for higher capacity batteries.

Another example is the use of eco-friendly and low-cost cellulose. For example, the composite of carboxyl methylcellulose (CMC) and polyvinyl alcohol (PVA) with graphene nanospheres added with aluminum oxide. The ability of CMC and PVA to swell in liquid

Fig. 18 Effect of addition of capacitive reinforcement like CNT and MnO₂ in the PANI-graphene matrix on their specific capacitance values.

Fig. 19 Nature and structure of monolayer, bilayer, and bulk heterojunction composite system and location of polymeric matrix composite layer in the solar cell.

electrolytes influenced the electrical properties of graphite electrodes. The CMC allows the bridging between electrolyte and electrode component and impart excellent charging and discharging capabilities for higher cycles (Nirmale *et al.*, 2017).

Solar Cells

Photovoltaic cells have recently gained tremendous attention as the replacement of the conventional silicon-based solar cells. Most of the photovoltaic cells have organic constituents because of which they are flexible, easy to process, and efficient. Although, a single polymeric system of such cells has instability under the exposure of oxygen, UV light, and humidity. Thus, multi-functional composite material such as an indium-doped tin oxide (ITO)/polyethylene naphthalate (PEN), which have excellent UV and oxygen resistance, were widely used in modern solar cells.

Fig. 19 shows the nature of the first three types of composite systems and the location of the polymeric matrix composite layer in the solar cell.

The monolayer solar cell comprises the polymeric composite of semi-conductive nature. Generally, poly(ethyleneimine) (PEI) and poly-(ethyleneimine)-ethoxylated (PEIE) matrix were used for the preparation of such composite. To increase the semi-conducting behavior, the polymer matrix was intensively doped with ZnO-graphene core-shell type quantum dots. The quantum dots play a multi-functional role as surface modifier, sub-photosensitizer, and electron transport layer. The transport layer shifts the charge to zinc oxide particle and then carries forward the charge to the graphene sheet. This path and rapid jumping of the

Table 5 Effect of nature and treatment of CNT in P3HT matrix on the open voltage of the solar cell

Sr. No	Nature of CNT	Treatment on CNT	Additive system	Matrix phase	Dose of CNT (%)	Open circuit voltage (mV)
1	MWCNT	Acid treatment – H ₂ SO ₄ and HNO ₃	PCBM	P3HT	1	570
2	MWCNT	Octyldecylamine	PCBM	P3HT	1	560
3	MWCNT	Carboxylated and sulfonated	C60	P3HT	1	386
4	DWCNT	75% HCl treatment	PCBM	P3HT + BDQF	1	530
5	SWCNT	Acid treatment, SDS treatment	–	P3HT	1	750
6	SWCNT	Acid treatment – H ₂ SO ₄ and HNO ₃	PCBM	P3HT	1	540
7	SWCNT	Non-covalent functionalization with the polymer	–	P3HT	1	580

Abbreviation: PCMB, (6,6)-phenyl-C61-butyric-acid methyl ester; BDQF, 2,7-Bis-(3,3''didodecyl-[2,2',5',2'',5'',2'''] quaterthiophen-5-yl))-fluoren-9-one; SDS, Sodium dodecyl sulfate.

charge increase the efficiency of the chain. Similarly, the thin nanocomposite film of poly(9,9-di-*n*-octylfluorenyl-2,7-diyl)(F8) blended with poly(9,9-dioctylfluorene-*alt*-benzothiadiazole)(PFB) matrix reinforced with nickel and zinc oxide on to the ITO electrode shows excellent electrical semi-conduction properties. PFB capping layer effectively reduced the performance of the device due to its blocking of photogenerated electrons in the F8-rich phase from reaching the electrode.

The modification of F8 and PFB with different layers encourages the concept of the bilayer polymer composite where the one phase will be the donor phase, and others will be the acceptor phase. The use of bi-layers structure decreases the recombination probability of the carriers because the free charge carriers migrate in their respective domains towards the electrodes. In such composite PFB layer is commonly used as the donor and F8BT (poly(9,9'-dioctylfluor-ene-*co*-benzothiadiazole)) as the electron acceptor (Borges *et al.*, 2018).

Polymer-polymer composite solar cells can be constructed using a phenyl octyl-substituted polythiophene derivative with donor and acceptor layer resulted in higher efficiency under full air mass 1.5 illuminations (100 mW/cm²) (Hoppe and Serdar, 2008). Bilayer polymer composites of multi-wall carbon nanotube and poly(3-hexylthiophene) (P3HT) were also explored in the polymer-inorganic regime for solar cell application. Table 5 enlist the matrix and CNT combination with various additive systems and intent to compare the open circuit voltage of the composites. This composite helps in enhancing the thermal stability of the solar cell and imparting the excellent performance properties – the addition of multi-wall carbon nanotubes in polymer matrix increases the open-circuit voltage of the solar cell, the multi-wall structure helps in maintain the potential throughout the matrix.

The last type of polymer composite solar cell is of bulk-heterojunction (BHJ) design; these design forms the donor/acceptor interface at the molecular scale and increases the exciton dissociation sites. Higher the number of sites will improve the light-induced flow of electron and thus improve the conversion efficiency. The new example BHJ type solar cell composite is PEDOT: PSS arranged in the layer composite with gold and modified graphene nanoparticle and sandwiched between electrode layers (Rezaei *et al.*, 2019). In this, the gold nanoparticles with graphene shell (Au NPs-Gr), positioned between hole transport and active layers. The graphene shell improves the intactness of the gold particle within the bulk-heterojunction layer and thus facilitated charge transfer in the solar cell. Because of which the open-circuit voltage of the solar cell improves by 42% when compared with the conventional solar cells. Most functional polymeric composite of PANI is widely used as the heterojunction phase coupled with the PEDOT system. The bulk junction of carbon nanotubes was created in the PANI matrix, because of which the bandgap in the structure can be tuned for low light solar cells.

Piezoelectric Components

Generally, the piezoelectric effect constitutes certain behavior of polymeric material because of which they generate an electrical potential whenever exposed to mechanical stimuli. The crystalline part of the polymer produces electrical charges across the lattice boundaries or chain boundaries in response to the applied force or pressure. Polymeric matrix-like polyvinylidene fluoride (PVDF) and its copolymers, cellulose and their derivatives, polylactic acids (PLA), polyurethanes (PU), polyimides (PI) show inherent piezoelectric performance. When these polymer matrices were mixed with ceramic particles, their ability to generate charge increases. For example, the composite of polyvinylidene fluoride hexafluoropropylene (PVDF-HFP) and ceramic barium titanate nanoparticles (BaTiO₃) with additional reinforcement of the hexagonal boron nitride (*h*-BN) nanolayers. The composite showed excellent piezoelectric output voltage (2.4 V) with high dielectric constant (45) and low dielectric loss (7.8). The PVDF phase allows the absorption of the mechanical force or pressure applied to it and transmits the force towards the localized ceramic particle. Ceramic particle exhibits ferroelectric properties because of which a higher potential was created along the boundary. This effect gets aggravated in the presence of hexagonal boron nitride. The hexagonal structure of boron nitride or white graphene possesses excellent dielectric properties with excellent mechanical strength and oxidation resistance. Because of which the addition of hexagonal boron nitride with BaTiO₃ allows the designer to tune the composite according to the application (Ponnamma and Al-maadeed, 2019).

Li₂CO₃/PVDF based composite has demonstrated improvement in the dielectric and piezoelectric properties with maintaining the flexibility of the composite. Instead of such a versatile nature, the PVDF based composite was not ideally used for high-

temperature applications. At high temperature, the phase transformation from polar β -phase to nonpolar α - and γ -phases of PVDF occur because of which the matrix loses its electromechanical properties.

Poly(γ -benzyl- α , L-glutamate) (PBLG) is one of the emerging polymer matrices which shows the piezoelectric behavior like PVDF and thermally stable at high temperature. PBLG allows the scouting of the polymer-polymer composite in the piezoelectric application. PBLG has well defined helical conformation, which causes axial orientation and thus generate polarization in the presence of shear force. Polarization in the structure draws the balance between positive and negative charge in the structure. The PMMA/PBLG composite with 30% PBLG reinforcement has durable piezoelectric behavior with excellent chemical resistance.

Polyvinyl alcohol (PVA) is a good insulating material with low conductivity, hence it is very useful in microelectronic industry. For example, barium titanate reinforced polyvinyl alcohol have shown frequency and temperature dependence dielectric behavior. Stable dielectric properties make the PVA/barium titanate polymer ceramic composites as a good candidate material for various industrial applications. PLA-based polymers are becoming a popular candidate for energy harvesting applications owing to their higher piezoelectric properties.

Others

Flexible conductors

Flexible conductor made up of polycarbonate/PMMA matrix reinforced with SOCl_2 modified SWCNT composite showed five times higher electrical conductivity as compared to the normal polymeric matrix. In such a composite, the optical transparency is dependent on the SWCNT. The higher loading of the SWCNT may drop the transparency. Although, in current literature, it was found that the addition of 0.1%–0.5% of SWCNT in the polymeric matrix shows 92% of optical transparency in the composite (Dettlaffeglikowska *et al.*, 2006). The flexible conductors were also constructed using the HDPE matrix imbedded with iron nanoparticle. The 7% acid-coated iron nanoparticle have been dispersed in the HDPE matrix in support of PANI short fibers. The iron nanoparticle with PANI fibers helps in enhancing the electrical conductivity of the composite, and chemically inert nature of the HDPE matrix allows the use of such composite in reactive sensors circuit. Where the sensors are in direct contact with the reacting liquid or compounds.

Microelectronics

Microelectronics includes the smaller design component like diodes, transducer, and resistors made up of semiconducting materials. Polymer composite light-emitting diodes and polymer light-emitting electrochemical cells have attracted broad interests due to their large potentials in serving as next-generation displays and illuminants. Composite of poly(para-phenylene) matrix with carbon fiber reinforcement have exhibit high photoluminescence (PL) in the blue color region with excellent quantum yields, charge-carrier mobility, and good processability. Poly[2,7-(9,9'-dioctylfluorene)-*alt*-1,3-(5-carbazolphenylene)] (PFCz) composite with secondary phase of zinc oxide have found wider application in UV blue-light-emitting systems. Similarly, conjugated fluorene-*alt*-pyridine and fluorene-*alt*-thiophene polymers containing phosphorescent iridium base composite shows phosphorescent quantum yield and thus have superior light-emitting. Similarly, the use of arranged CNT array in the PDMS matrix imparts anisotropic thermal conductivity, which provides an effective path for the frequency control of the optoacoustic devices used in the biomedical industry (Li *et al.*, 2020). The dropping of carbon nanotubes and ethoxyethanol on the polyethylene microsphere composites are widely used in the frequency modulation of the laser ultrasound transducer.

Solder joints

A polymer-metal composite can be used as a solder material, where polymer acts as a binder and metal power, such as silver acts as a thermal conductor. The CNT-silver base reinforcement was dispersed in epoxy-based conductive adhesives and used for soldering the joints in printing circuit boards. The resistivity of 66.5 wt% silver-filled conductive adhesive without CNT loading had $10^4 \Omega \text{ cm}$, whereas $10^4 \Omega \text{ cm}$ of resistivity was shown for adding 0.27 wt% CNT, which shows that the polymer composite adhesive can replace conventional silver metal filler. Recently the development of lead-free soldering adhesive has attracted high commercial interest. Polyimide-siloxane base composite with graphene and metal particles have established a significant market for such adhesive. The metal particle insured the distribution of heat energy. It enhanced the thermal conductivity of the adhesive, whereas the polymer matrix and graphene fill the ruptured gap and hold the component at its place.

Summary

This article provides a broad picture of the structure, properties, and application of the multifunctional polymer matrix composite. Almost every example provided within the article intends to project the degree of multifunctionality present or required for the application. The combination of different properties associated with matrix, reinforcement, and structural diversity of multifunctional composite helps in designing new material which has tremendous application the filed construction, automobile, mechanical devices, sensors, packaging safety devices, solar cells, and energy-conserving devices. In many cases, the strength of material and density are the factors for design consideration, whereas, in other stimuli response, thermal stability and conductive properties are of main interest. In some example, the multi-functionality is the matrix-based response. In contrast, other examples

may show reinforcing component base multifunctionality in the case of structural application, the design and structure of composite play a vital role. The design and the interaction of the matrix and fiber in layer or dispersed form decide the degree of multifunctionality and suitability of polymer matrix composites. For stimuli-responsive application, the chemistry of matrix and reinforcement have higher importance than that of its structure. The chemical functionality in the composite decides the multiple responses of the composite against single or multiple stimuli. In the case of high-temperature applications, the chemistry, morphology, and thermal properties are the points of considerations with other functional properties like density and processability of the composites. Similarly, the composites in batteries, solar cells, and electronics applications require such polymeric matrix composite, that can constitute excellent electrical properties with chemical inertness and mechanical stability. All of such modern application requires the combination of different properties which multi-functional polymeric composite can easily serve.
